The first impression made by James Spence on visitor and colleague alike came from his charm. In his own home, taking tea with sisters and residents on the wards, in the meetings of his department, or as president of the local medical society, he was always the gracious and charming host. But to remain here would be to miss the measure and the nature of his greatness. He was a fine clinician; yet he made no outstanding discoveries in clinical medicine. He started his career as a biochemist, and almost his last communication was entitled the Methodology of Clinical Science; yet he was not essentially a medical scientist. Perhaps a friend came near to the heart of the matter in describing him as "an artist who had survived a scientific training."

If this estimate is true then the first and maybe the greatest expression of his sensitive insight into the nature of family life was the creation of the Babies' Hospital where the mothers were admitted to nurse their own children. The second was the binding together in mutual inquiry of the university department and the local health authority. But it was in the conception and creation of the university department that his sensitivity and strength found their fullest expression.

The simple but profound conviction which guided his thinking in this field I first learnt from the postscript to a card telling me the arrangements for my coming to Newcastle: it ran as follows. "The first aim of my department is comradeship not achievement." Friendship between all concerned with the care of children in Newcastle was the catalyst which brought into being the combined medical and surgical units, the clear definition of the aims and instruments of undergraduate teaching, and the varied pattern of clinical and social investigation which he developed in the last years of his life.

He was a great teacher of the gifted student; those who were seeking a main road to the final examination often found his exacting standard of clinical accuracy and his unpredictable questions too much for them. They recognised that "despite the manner of a kindly patrician he was a dangerous man." He was at his best when faced with the swift and calamitous illness in the ward, or painting a vivid picture of disease in the

20 minutes of a clinical lecture, and above all in sensing and handling the hidden fear of a mother in consultation.

Those of us who owe so much to this generosity find it difficult at this time to speak of his faults. His loyalty, which was often less critical than was good for us, made us all temporarily a little larger than life size. His quick intuitive mind had a distrust of the typewriter, the memorandum, and all the wordy planning of modern administration. In consequence our first awareness of the visit of a distinguished visitor would often be their appearance in the ward or outpatient clinic with the introductory greeting from James Spence "this is Professor — who will be with us for the next fortnight and I know I can leave him in your care."

He had too a love of the novel and the unexpected—new faces, new stories, and new ideas—and a capacity for distilling their essence and adding it quickly to his current counsel which, though refreshing, sometimes led to a superficiality of judgment. Yet even when you felt most sure he was wrong, you always emerged wiser from the encounter. James Spence, artist and scientist, romantic and realist, conservative and rebel, was always a leader.

Births, Marriages, and Deaths

BIRTHS

DAVIES.—On June 1, in London, to Dr. Cella Marjorie Davies (formerly Rapport), wife of Dr. D. L. Davies—a son.
 PYKE.—On June 6, at the Radcliffe Infirmary, Oxford, to Janet, wife of Dr. David Pyke—a daughter.

Appointments

GLENNIE, R. E., M.D. Aberd., D.O.B., D.P.M.: consultant child psychiatrist, Cambridge area.
 JACKSON, RUBY M., M.B. Sheff., D.OBST.: asst. county M.O., North East Kent.
 MOIRAN, J. M., M.B. Glasg., D.P.H.: executive M.O., west area Northumberland, M.O.H., urban districts of Hexham and rural districts of Bellingham, Haltwhistle, and Hexham.
 MACRAE, A. K. M., M.B. Edin., M.R.C.P., DIP. PSYCH.: physician-superintendent, Bangour Mental Hospital, West Lothian.
 PATERSON, WILLIAM, M.B. Glasg., D.P.H.: M.O., Cornwall, school M.O. and M.O.H., area 6.
 SMITHAM, J. HILLYER, M.B. Lond., F.F.R., D.M.R.E.: part-time diagnostic radiologist (consultant status), Chelsea Hospital for Women, London.
 WILSON, H. B., M.B. Aberd., F.F.A. R.O.S., D.P.H., D.A.: senior anaesthetist, University of Aberdeen.
Manchester Regional Hospital Board:
 HARVEY, P. W., M.B. Manc., DIP. PATH.: consultant pathologist, group laboratory, Victoria Hospital, Blackpool.
 SHANNON, T. E., M.B. N.U.I., D.O.M.S.: consultant ophthalmologist, Bolton and district hospitals.
 WILSON, T. MCS., M.C., M.B. Edin., M.R.C.P.: consultant chest physician and physician-superintendent, Baguley Hospital.

Notes and News

AT HOME IN THE HOSPITAL

DREAD of hospitals, though less common than it was, is still severe enough among the few to deserve a place with the other phobias. We recommend to those who suffer from it a good prophylactic in the form of a book¹ just published on behalf of the Middlesex Hospital. Here nearly all the activities of a hospital are shown, in really splendid photographs, and explained in a minimum of text. Mr. Derek Adkins, the photographer, followed individual patients with typical diseases through every stage of their treatment, beginning at the moment when they were first seen as outpatients. He attended operations, watched fractures reduced, saw the pathology department examine slides for tubercle bacilli, watched X-ray diagnosis and treatment, and photographed these and many other medical and surgical procedures. He also visited the kitchens, the laundry, the storerooms, the engineers' department, and the dispensary; he arrived for the milk delivery, and went to Covent Garden with the hospital florist; he attended an evening meeting in the boardroom, and a Sunday morning service in the chapel. From his 850 photographs 150 were chosen to appear in this book, and these present the daily work of a great hospital in a way that has not been done before.

The patients' histories are perhaps the most telling part of this persuasive work. The boy who fractured his ankle in a motor-bicycle accident is seen, at the end of his stay in hospital, riding confidently away on the same machine; the medical student whose miniature radiograph showed tuberculosis is eventually passed fit to return to his career; the diabetic settles down at home to his régime, under the guidance of a social worker who is herself a diabetic; the blue baby tricycles triumphantly round the ward. Perhaps the most reassuring case of all is that of the gastric ulcer patient who came in looking an old sick man, and went back to work, after partial gastrectomy, apparently twenty years younger.

As Colonel Astor, the chairman of the Middlesex, notes in his introduction, a far larger book would be needed to outline the work of every part of the complex organisation which is a hospital. The purpose of this small work is, first, to give an impression of the way a modern hospital staff go about their duties, and how numerous and varied are their callings: and this it does to perfection. Its second aim is to add to the confidence of the patient in those who are looking after him, for this, as Colonel Astor says, is a factor of unchanging importance in his recovery. This book should do much to establish such confidence.

DOCTOR AND ENGINEER IN PUBLIC HEALTH

ADDRESSING the Institution of Sanitary Engineers, on April 3, Dr. R. F. Guymer, Rockefeller tutor in public-health engineering at the London School of Hygiene and Tropical Medicine, said that if any good is to come of the liaison between doctors, engineers, and others, we must guard against adopting a too local and a too parochial attitude. Such labels as preventive medicine, social medicine, and environmental sanitation are unimportant: the basic principles are what matter.

In his "Report of a general plan for the promotion of public and personal health in the State of Massachusetts," published in 1850, Lemuel Shattuck, the Boston bookseller, proposed that a general board of health should be created, consisting of two physicians, one counsellor-at-law, one civil engineer, one chemist, and two persons of other professions or occupations. His reasons for giving the board this constitution were, first, that many questions would arise requiring knowledge possessed by different professions, and secondly that the promotion of public health is a matter that concerns every profession and every person. This was perhaps the first mention of a great basic principle: that the promotion and maintenance of health is not the prerogative of any one section of the population or of any one profession; it is the concern of everyone to a greater or less extent.

Today, said Dr. Guymer, the creation and maintenance of good health depend upon team-work, and he drew examples from Ceylon, Egypt, and America. Many years ago Ceylon possessed a good irrigation scheme which was largely responsible for the prosperity of the island; but it was seriously upset by invasions in the 14th and 15th centuries, and malaria became a scourge of the population. In this century, besides

installing new irrigation it has been necessary to try to stamp out malaria, and such progress has been made that there is no reason why the island should not regain its former prosperity. In Egypt in modern times irrigation improved to such an extent that two or even three crops were grown in a year; but unfortunately the new system produced ideal conditions for the water-snail which harbours bilharzia. The consequent advance of bilharziasis illustrates how, in the absence of team-work and foresight, improvement in one environmental factor may increase an already existing endemic disease. The American example was of the Tennessee Valley project where, up to 1933, an area of more than 60,000 square miles was for all practical purposes derelict, largely because of malaria. Such persons as lived in the area were so diseased that they possessed neither the physique nor the morale to remedy their plight. To develop this area the Tennessee Valley Authority employed nearly 40,000 persons, including engineers, doctors, chemists, entomologists, agriculturists, architects, and veterinary surgeons. A length of the Tennessee River, over 600 miles in extent, was divided into a series of lakes or reservoirs by the building of dams, and to remove mosquito breeding-places a strip of the river bank between the highest water level and the top of the bank was cleared of vegetation. By operating the sluice-gates of the dams, the water level is raised in winter above its highest normal, in order to strand floating debris; this level is maintained during early spring (the mosquito breeding-season) so that the water shall never be stagnant; and in late spring and summer the level is raised and lowered weekly so as to strand the mosquitoes on the dry sun-baked earth where they cannot live. Other problems solved included the supply of water and electricity, the restoration of fertility to the land, with lessening of soil erosion, and the provision of seed and fertilisers. Gradually this desert area began to blossom as a rose.

Such enterprises, said Dr. Guymer, are of great importance; for the world population is increasing, and it is imperative that places which are at present barren and useless should be developed and transformed into places where man can live healthily and happily. By such work, he believed, we shall make a very real contribution to the establishment of a lasting peace; for people who are housed, fed, and clothed adequately, and who can work and relax in congenial surroundings, free from disease, are probably less likely to resort to war to settle their disputes.

MASSON ET CIE

Masson, the well-known French medical publishers, celebrate their 150th year with a handsomely printed and illustrated monograph.¹ The firm began life as the Librairie Médicale et Scientifique in 1804, in an era when, under the First Empire, many educational reforms were being made in France and the growing importance of the natural sciences was creating a need for better textbooks and journals. Victor Masson (1807-79) joined Nicolas Crochard, the founder, in 1838 and became sole owner eight years later. He brought original ideas to scientific publishing; he improved the format of textbooks and introduced the use of illustrations both in the text and by engraved plates. He also realised the importance of exporting medical and scientific books, both for trade and as a means of maintaining the prestige of French culture. He was succeeded in 1859 by his son Georges Masson; and the present Georges Masson, his great-grandson, who is one of three co-directors, carries on the family connection with the firm. Since 1904 Masson et Cie have published the *Presse Médicale*. This firm's publishing programmes since the war show that venerable age has not impaired its vigour.

POSTS IN NIGERIA

In an advertisement in this issue the Colonial Office invite applications for posts in the medical department of the Northern Region of Nigeria. But the Colonial Office feel that British doctors may hesitate to join the service without formal reassurance as to their future prospects, and they have accordingly sent us a statement issued in Lagos last January by the heads of Nigerian delegations on the future employment of overseas officers in their public services.

The heads state: "We are determined to press forward with the Nigerianisation of the Civil Service; but we are aware that the efficient administrative machinery which the country

1. Hospital at Work. Published for the Middlesex Hospital by Max Parrish. 1954. Pp. 48. 3s. 6d.

1. 1804-1954: Masson et Cie. 120, Boulevard Saint-Germain, Paris 6^e.

must have cannot, as yet, be provided unless a sufficient number of experienced and qualified overseas officers continue to be available." They go on to declare their intention to safeguard the interest of overseas officers and to "assure them that future terms and conditions of service will be fair and reasonable and no less favourable than those obtaining today." They also state that they support the principle that all public-service questions—including appointments, promotions, transfers, postings, dismissal and other disciplinary matters—should be kept independent of political control, and that they hope that the traditional principle of promotion according to qualifications, experience, merit, without regard to race, will be maintained.

University of Cambridge

On May 29 the following degrees were conferred :

M.D.—J. D. Lever.

M.B., B.Chir.—A. E. Gibbs, *J. H. H. Webster.

M.B.—J. D. Salmon.

* By proxy.

Faculty of Anaesthetists

At a meeting of the board of the faculty, held on June 2, at the Royal College of Surgeons of England, Dr. Bernard Johnson was re-elected dean, and Dr. R. F. Woolmer was elected vice-dean for the ensuing year.

Scottish National Health Service Tribunal

Mr. I. H. Shearer, q.c., has been appointed chairman of the tribunal in succession to Mr. William Grant, q.c., who has resigned.

La Semaine Médicale de Paris

This year the meeting will be held in Paris from Oct. 3 to 10. As last year, most of the meetings will be held at the Salpêtrière.

London Medical Orchestra

A section of this orchestra will play music by Purcell, Bach, and Mozart at a meeting of the London Association of the Medical Women's Federation at the Royal Free Hospital School of Medicine, on Friday, June 18, at 8.15 P.M.

Military Appointments

Sir Arthur Porritt has been appointed honorary consulting surgeon to the Army at home, in succession to Sir Heneage Ogilvie; Mr. J. B. Blaikley has been appointed honorary consultant in gynaecology to the Queen Alexandra Military Hospital, Millbank, in succession to Mr. Frank Cook.

The Physician and Traffic Safety

The International Union of Associations of Doctor Motorists has chosen this subject as the main topic of its first post-war congress, which is to be held in Vienna from September 8 to 11. Further particulars may be had from the Secretariat of the Ärztliche Kraftfahrvereinigung Österreichs, Vienna 1, Weihburggasse 10-12, Austria.

Hospital Research Prizes

The board of governors of Queen Charlotte's and Chelsea Hospitals have awarded a prize of £200 to Mr. J. H. Gibson for his paper (written with Dr. R. M. Calman) on Pyrexia in the Puerperium with particular reference to Uterine Infections, and a prize of £50 to Dr. W. E. Hunt for his paper on Acute Oesophagitis in the Newborn Infant.

International Award

An international award is planned to honour outstanding workers in the field of the venereal diseases and non-venereal treponematoses. If sufficient funds are collected the award will be administered by W.H.O. In the United Kingdom cheques, payable to the International Treponematoses Award Fund, should be sent to Dr. R. R. Willcox, St. Mary's Hospital London, W.2.

Electronics Exhibition

This exhibition, which is to be held at the Manchester College of Technology from July 14 to 20, will include several medical exhibits. The Christie Hospital and Holt Radium Institute is showing a scintillation dose-rate meter, a dose-rate comparator, and a dose-rate and integrating dose monitor for use with an X-ray tube; the Institute of Cancer Research of the Royal Cancer Hospital, ultrasonic echo locating equipment; and the Burden Neurological Institute a portable 12-channel toposcope. Further particulars may be had from the secretary, Mr. W. Birtwistle, 78, Shaw Road, Thornham, Rochdale.

Medical Insurance Agency

The annual meeting of this agency was held on June 3, with Dr. James Fenton in the chair. The committee of management reported that in 1953 the net profit was greater than ever before: this is distributable solely to the medical and dental charities. The total of rebates of premiums granted to clients also reached a new peak. Dr. Fenton was re-elected chairman, and Dr. Henry Robinson hon. secretary. The following retiring members of the committee were re-elected: Dr. J. A. Brown, Dr. J. T. Ingram, Dr. G. Roche Lynch, Sir Henry Souttar, and Prof. R. J. Willan. New members elected were: Prof. Alan Kekwick and Prof. G. A. Wishart.

Lord Webb-Johnson has been appointed consulting surgeon to the Royal Dental Hospital of London and School of Dental Surgery.

The second edition of the *Directory of International Scientific Organizations* has been published by UNESCO. Copies may be had from H.M. Stationery Office (13s. 6d.).

Diary of the Week

JUNE 13 TO 19

Monday, 14th

POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.12
4 P.M. Dr. H. E. Holling: Ballistocardiography.

INSTITUTE OF NEUROLOGY, The National Hospital, Queen Square, W.C.1

5 P.M. Dr. E. H. Botterell (Toronto): Management of Spinal-cord Injuries and Studies on Spinal Man.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY

3 P.M. (Chelsea Hospital for Women, Dovehouse Street, S.W.3.)

Prof. J. Louw (Cape Town): Abortions.

4.30 P.M. Prof. Bruce Mayes (Sydney): Infertility.

Tuesday, 15th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1

5 P.M. Dr. J. L. Livingstone: Treatment of Pulmonary Tuberculosis at the Present Time. (Mitchell lecture.)

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2

3.45 P.M. Prof. M. F. Lucas Keene: Embryological Background of Some Common Abnormalities. (Arnott demonstration.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1

8 P.M. *Section of Psychiatry*. Dr. V. E. Frankl (Vienna): The Concept of Man in Psychotherapy.

POSTGRADUATE MEDICAL SCHOOL OF LONDON

4 P.M. Dr. A. M. Cooke: On Writing for a Medical Journal.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2

5.30 P.M. Dr. W. N. Goldsmith: Tuberculosis.

Wednesday, 16th

INSTITUTE OF DERMATOLOGY

5.30 P.M. Dr. C. D. Calnan: Ringworm Infections and Their Treatment.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY

NOON (Queen Charlotte's Hospital, Goldhawk Road, W.6.)

Professor Mayes: Could the Chapter on Eclampsia Disappear?

Thursday, 17th

ROYAL COLLEGE OF SURGEONS

5 P.M. Sir Stanford Cade: Adrenalectomy. (Hunterian lecture.)

POSTGRADUATE MEDICAL SCHOOL OF LONDON

4 P.M. Dr. Cooke: Medical Writing from MS. to Reprint.

INSTITUTE OF DERMATOLOGY

5.30 P.M. Dr. H. Haber: Specific Granulomas.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY

3 P.M. (Hammer Smith Hospital, Ducane Road, W.12.) Professor

Mayes: The Pregnant Diabetic.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 26, Portland

Place, W.1
7.30 P.M. Dr. C. C. Chesterman: Training and Employment of African Auxiliary Medical Personnel.

Friday, 18th

POSTGRADUATE MEDICAL SCHOOL OF LONDON

2 P.M. Mr. J. Ellsworth Laing: General Principles of Plastic Repair.

4 P.M. Dr. Douglas Hubble: Investigation of Endocrine Syndromes.

MEDICAL RESEARCH SOCIETY

5.30 P.M. (London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1.) Dr. G. W. Thorn (Harvard): Adrenal Cortical Response to Stress in Man.

INSTITUTE OF DERMATOLOGY

5.30 P.M. Dr. R. M. B. MacKenna: Tuberculosis and Sarcoid.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY

2 P.M. (Queen Charlotte's Hospital.) Professor Louw: Rupture of Uterus.

Saturday, 19th

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY

11 A.M. (Chelsea Hospital for Women.) Mr. C. Kimbell:

Subtotal, Total, and Vaginal Hysterectomy.

BIOCHEMICAL SOCIETY

11 A.M. (Department of Biochemistry, University of Cambridge.)

Scientific papers.

THE ABUSE OF REST *

W. MELVILLE ARNOTT

T.D., B.Sc., M.D. Edin., M.D. Birm., F.R.C.P., F.R.C.P.E.
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF BIRMINGHAM

THE *Concise Oxford Dictionary* defines rest clearly enough as "repose or sleep especially in bed at night; abstinence or freedom from or absence of exertion or activity or movement or care or molestation." But there are few terms in the English language which possess such a complex superstructure of special meaning and oblique implication as this simple monosyllable. Take for instance its use in relation to gainful employment, of which it is the antithesis. No less an authority than George Schwartz, writing in the *Sunday Times* of Sept. 6, 1953, states (as usual, with his tongue in his cheek) that "if there is one thing that justifies man's claim to be only a little lower than the angels it is that the human race is not fond of work for work's sake."

Rest has an aura of desirability because work includes, or has included, an element of exploitation. Everybody would agree that a week of 70-80 hours toiling in the "dark satanic mills" of the Industrial Revolution was intrinsically harmful, but when a claim is made that to work for more than 40 hours per week in a modern engineering works is unhealthy one is not really expected to believe that it is the toil itself that hurts. Such a claim is merely a move in the complex adjustment of remuneration—the setting of the dividing line between normal and overtime rates.

Consider further the widespread belief that hard work, with its mental and physical activity, plays an important part in the causation of disease. This belief has little rational basis; it does not rest on a critical analysis of the physiology of activity; and it is not attached to any demonstration of damage by repeated muscular contraction, by the elevated metabolism of effort, or by concentrated thought. Indeed there is abundant evidence that none of the known effects of work can harm healthy tissues. On the contrary all these effects are, in a different context, regarded as beneficial in the sense that they develop and extend the range of adaptation of physiological mechanisms.

The evil reputation of work as a cause of disease springs from two rather disreputable and quite illogical traits in human character. The first is the widespread reluctance of medical men to admit frankly that they are ignorant of the cause of disease—that they do not know why a particular person has fallen victim to an infection or why another person's blood-pressure has risen or a clot formed in his coronary artery. The second is the very understandable but really quite indecent avidity with which a patient accepts the explanation that his illness is due to overwork and insufficient rest. It is a belief which nourishes his amour-propre; it enrols him in the noble army of martyrs; he has fallen fighting the good fight. Believing this, he can relax with a clear conscience and enjoy to the full the provisions of a Welfare State, the bondage of a possessive wife, and the plaudits of an admiring family. In brief the general implication is that work is hell and rest is heaven as implied in the words of the lovely hymn which refers to "the saints who from their labours rest."

I am sure then we should all agree that work—even hard work—which involves no avoidable hazard, does not interfere with sleep or nutrition, which is remunerated sufficiently to remove any sense of exploitation, and which allows of enough recreation to counteract tedium, is harmless. Indeed, it is beneficial. One cynic has said that the chief aim of life is to fill in the time between

birth and death—which is perhaps why medicine is so popular a profession, for we can all at least be sure that our work will fill our thoughts and direct our activities from when we wake in the morning until late at night we go wearily to bed.

* * *

Now if rest in general were as blameless a state as work there would be no question of abusing it. If the possibility of abuse was merely negative—in that at worst the prescription of rest could do no more than exclude other more useful measures—it would hardly deserve comment. But the truth is that in overdose rest is very toxic and even lethal, and should be classed as one of the most powerful of the "drugs of addiction." Indeed, like morphine, cocaine, and the others, it should be included in the scope of the Dangerous Drugs Act and be prescribable only in clearly defined doses not to be repeated without a further prescription. Of course in a sense this is so, since certificates of incapacity have to be repeated at regular intervals; but all too often repetition is the rule rather than the exception.

Using the term as indicating certified incapacity for normal gainful occupation there are degrees of rest ranging from immobilisation in a plaster cast to a régime of rehabilitatory exercise which make the patient's ordinary occupation a rest-cure by comparison. Rest in bed has come to occupy a large place in current therapeutics: in fact it is widely regarded as normal for the sick person to be in bed. The attitude is such that the burden of proof is on the physician who says the patient should not be in bed, rather than the reverse which I believe is the only logical position. Surely it is normal for a person to be mobile and absurd for him to spend all or most of his time in bed. Once that is accepted—and it is irrefutable—then it becomes illogical to allow or encourage confinement to bed without good and sufficient evidence of its beneficial effect. The difference between the doctor who practises intelligently and with judgment and one whose activities consist in some rather simple conditioned reflexes is that the latter sees nothing incongruous in ordering bed rest without proof of its beneficial value, just as he prescribes iron, vitamin B₁₂, and folic-acid pills in unspecified anaemia or puts all his patients on multiple vitamin pills despite the overwhelming evidence of the rarity of vitamin deficiency in this country. To treat without reason is to ape the witch-doctor and to defend such action by pleading that the patient expects it is a contemptible retreat from reason.

There is abundant evidence that the mere act of immobilising a man produces profound changes in metabolic function. Deitrick, Whedon, and Shorr¹ reported a well-controlled study of the effects of immobilising young healthy men for periods of six or seven weeks. Among the changes observed were (1) negative nitrogen balance to an average extent of 54 g.; (2) a total calcium loss of 9-24 g. This excretion of calcium, combined with unchanged urinary volume, a slight rise in urinary pH and a failure of urinary citric acid to rise, all favour the precipitation of calcium phosphate in the urinary tract. Normal calcium metabolism was not resumed until six weeks after the rest period. Circulatory changes brought about by immobilisation were a decline in total blood volume and a deterioration in the mechanisms essential for adequate circulation in the erect position as indicated by an increased tendency to faint in tilt-table tests. The legs seemed to be the principal site of changes responsible for this deterioration—changes such as venous engorgement, capillary fragility, and impaired muscle tone. Exercise tolerance, leg girth, and pulse-rate took approximately six weeks to return to normal.

* From an address to the Section of Medicine, Royal Society of Medicine, Nov. 24, 1953.

This work shows that, even in the healthy young adult, immobilisation causes profound metabolic changes. However, it has long been evident to clinicians that a long sojourn in bed has harmful results, particularly if the patient be elderly. Skeletal changes, such as muscular contraction and wasting, joint malposition, and ligamentous stretching, are common. Urinary calculi can be caused by immobilisation in the horizontal position, while confinement to bed is an important factor in the all too common incontinence of the elderly—a defect which can often be terminated by getting the patient up. Probably the most disastrous complication of bed rest is the bedsore, which can be prevented only by continual attention to the pressure areas, demanding an amount of nursing care which is very hard to provide. Satisfactory alimentary function is very difficult to secure in the bedridden; anorexia and constipation are common. A welcome development in this respect is the increasing realisation that the efficient use of a bedpan is an athletic feat demanding a degree of training, coördination, and endurance which would do credit to the young and healthy. Except in cases of extreme paralysis and major fractures it is usually far better to help the patient on to a commode.

To summarise the harmful effects of bed rest I cannot do better than quote the vivid crescendos of Dr. R. A. J. Asher,² who in describing the evils of an overdose says:

“even those evils I have outlined may help to show that rest in bed is anatomically, physiologically, and psychologically unsound. Look at a patient lying long in bed. What a pathetic picture he makes! The blood clotting in his veins, the lime draining from his bones, the scybala stacking up in his colon, the flesh rotting from his seat, the urine leaking from his distended bladder, and the spirit evaporating from his soul.”

In the face of this damning indictment it is remarkable that bed rest should be used at all, and still more remarkable that it should be used to the extent implied in the threadbare joke “stay in bed till I come back.”

* * *

I cannot claim to have made anything more than a very superficial attempt to trace the history of bed rest as a therapeutic measure. It has, of course always been recognised that rest is essential for the acutely ill person, for no more profound reason than that bodily function is so disturbed that activity is distressing or even impossible. But there is little mention of bed rest in the 18th and early 19th century by such authors as Withering, Heberden, and Stokes. The medical history of John Hunter shows that he spent little time in bed during his various illnesses—though one must not deduce much from that, for he was the sort of rugged individualist who would ignore bodily distress and medical advice. The mid-19th century saw the impact of Hilton's *Rest and Pain*; and as I turned over its pages again there was borne in on me afresh the utter irrationality of therapeutics unrelated to the scientific study of disease. In case after case Hilton scored success, after all sorts of fantastic treatments had failed, because he recognised the value of rest in inflammation—particularly in osteomyelitis and bone and joint tuberculosis which was then so prevalent. As so often happens, opinion swung to the opposite extreme, and rest came to be regarded as the universal healer.

Another reason for undue emphasis on bed rest may be the tendency, since the 19th century, to treat illness in hospital rather than at home. In most hospitals, even today, the patient is expected to be in bed: the whole organisation is geared to such a state, and there is little provision for the up patient. Often, when the patient is admitted, the relatives take his clothes away, bringing them back only when discharge is imminent; for only a minority of hospitals have lockers or stores for the

retention of patients' clothing. Furthermore, the routine of the bed bath and the bedpan is firmly established in nursing care. Indeed, many of our older hospitals—especially those for the chronic sick, with large inadequately heated wards and too few nurses—enforce bed rest as the only *modus operandi*. The visitor to Continental clinics and to tropical hospitals cannot fail to be impressed by the extent to which patients get up and stroll around without any apparent harm—indeed much advantage.

* * *

Finally let me return to the wider question of rest in the sense of absence from employment.

In advising a patient not to work, the doctor assumes responsibility for (1) reducing the patient's income, (2) withdrawing several pounds per week from the Public Purse, and (3) reducing the efficiency of a factory or business: moreover at the same time he enforces on the patient an impression of the gravity of the illness. As these results of the certification of incapacity are obvious, such a costly prescription should never be written without a reasoned belief in its necessity, and the dose should be the minimum calculated to get the desired result. Yet nobody can for a moment suppose that such critical care is universal or even usual in either general or consulting practice.

One hears much of the inalienable right of a doctor to prescribe what he thinks is best for the patient but not enough of the inescapable duty of the doctor to reconcile the good of the patient with the good of the community of which the patient is a part. The vital importance of the welfare of the community as an extension of the welfare of the individual was brought forcibly home to me during the war, when for a time I was the medical specialist of a hospital in a beleaguered garrison. It required little imagination to see that every patient in hospital was one man less on the perimeter—rest was dispensed with rigid economy. If the same spirit pervaded the practice of medicine in present-day Britain there would be substantial advantage both material and moral. Excess prescribing of rest, and excess prescribing of drugs, are millstones around the neck of the health service and the nation—extravagances we cannot afford. Before he advises rest, let every doctor ask himself whether his prescription is really necessary, and, if it is, how little will suffice.

ACUTE APPENDICITIS IN LATE PREGNANCY*

R. B. PARKER

M.B. Edin., M.R.C.O.G.

LECTURER IN OBSTETRICS AND GYNECOLOGY IN THE UNIVERSITY OF BIRMINGHAM

WHEN acute appendicitis develops in a pregnant woman, a prompt diagnosis may be unusually difficult; for the abdominal pain and vomiting may be attributed to the pregnancy, and the physical signs are altered by the progressive enlargement of the uterus and by the corresponding displacement of the appendix towards the right flank. The difficulty in diagnosis is greatest in the later months of pregnancy, and not all workers are agreed on what is the correct treatment at that time. All previous papers on the subject in English have come from America, except individual cases. Fahmy (1944), for example, described a difficult case at the eighth month.

* The substance of this paper was presented at a joint meeting of the Birmingham and Midland and South-Western Obstetrical and Gynaecological Societies at Birmingham on May 7.

2. Asher, R. A. J. *Brit. med. J.* 1947, ii, 967.

The following case-records refer to patients admitted to the Birmingham Maternity Hospital in 1950-53 with acute appendicitis in the last trimester. The cases range from early to late or neglected admissions and are presented with the object of assessing the criteria of diagnosis and recording the results of treatment by appendicectomy with conservative management of the pregnancy.

Case-records

Case 1.—A woman, aged 31, was admitted as an emergency in the thirty-eighth week of her second pregnancy. Fifteen hours before admission pain came on in the centre of the abdomen, and after five hours it moved to the right iliac fossa. The pain was continuous and moderately severe, and the patient vomited soon after its onset. There was a history of occasional bouts of subacute appendicitis in the previous eighteen years, and on one occasion she had been admitted to hospital for observation but had no operation.

On examination her temperature was 99°F, pulse-rate 86, and tongue coated but moist. There were some guarding and tenderness on pressure in the right iliac fossa. The pregnancy appeared to be normal. On rectal examination no tenderness was elicited. Acute appendicitis was diagnosed.

Laparotomy was undertaken through a right paramedian incision eighteen hours after the onset of pain. Free turbid fluid was found in the peritoneal cavity. The appendix, lying alongside the cæcum, was acutely inflamed but not perforated. Appendicectomy was done, the stump was buried, and the abdomen was closed in layers. The patient received morphine and streptomycin.

Labour.—Twenty-four hours after operation labour began, and after five hours, when the cervix was fully dilated, forceps were applied under general anaesthesia. A healthy child was delivered. The patient made a good recovery, being apyrexial from the second day. There was no distension of the gut, and the wound healed by first intention.

Case 2.—A primigravida, aged 33, was admitted as an emergency, when thirty-nine weeks pregnant, with a history of sudden severe pain in the right iliac fossa coming on six hours before admission. The pain developed into a generalised ache across the lower abdomen. The patient had not vomited.

On examination the temperature was 100°F, the pulse-rate 98, and the tongue slightly furred but moist. The abdomen was a little tense; there was no true guarding or rigidity, but there was tenderness on deep pressure in the right iliac fossa. It was impossible to say whether the source of this tenderness was uterine or extra-uterine, because the pregnancy was filling the abdomen. There was no "release tenderness" or renal tenderness, and rectal examination revealed no abnormality. The foetal heart was heard. A catheter specimen of urine showed a moderate number of pus cells. The diagnosis rested between urinary infection, appendicitis, and accidental hæmorrhage. In view of the early stage of the condition it was considered proper to allow a short period of observation. Eight hours later the temperature was 98.4°F, and the pulse-rate 92; there was no vomiting and no alteration in physical signs. A further specimen of urine showed only an occasional pus cell. A further period of four hours' observation was undertaken, during which the patient had a sudden sharp attack of abdominal pain like the initial attack but felt in the midline above the pubis. The temperature was 99.2°F, and a white-cell count showed 18,200 leucocytes per c.mm. (76% polymorphs).

Laparotomy was therefore done twenty-one hours after the onset of symptoms. A McBurney incision was made and extended by cutting the muscle towards the loin. The appendix was found grossly inflamed but not ruptured, with fibrinous adhesions to the bowel. Appendicectomy was done, the stump was carbolised but not buried, and the abdomen was closed in layers. The patient received morphine and penicillin. Next day her condition was satisfactory and her temperature normal, but the foetal heart was not heard; it had last been detected four hours before laparotomy.

Labour.—Four days after the operation labour began spontaneously. After a first stage lasting eight hours a forceps delivery was undertaken under general anaesthesia, and a macerated baby was delivered. There was no evidence of accidental hæmorrhage or of any other reason for the intra-uterine death. The patient's progress continued to be

uneventful, and the wound healed by first intention. Nine months later she again became pregnant.

Case 3.—A primigravida, aged 29, was admitted, when thirty-seven weeks pregnant, with twenty-four hours' history of pain beginning in the epigastrium and settling in the right iliac fossa. She had vomited all food taken during this time. A record of her temperature taken before admission showed readings of 98.8° and 99°F.

On examination her temperature was 99°F, pulse-rate 90, tongue coated and dry, and the abdomen tender on pressure in both iliac fossæ, more notably on the right. There was no rigidity or guarding and no tenderness in the loins. "Release tenderness" was classed as doubtful. The uterus was of normal size for a pregnancy near term, and the foetal heart was heard. Rectal examination showed no abnormality. A catheter specimen of urine showed no pus cells but much acetone. The patient's doctor stated in his letter that she had a previous history of "indigestion" which could have been appendicitis; but on admission it was not felt that the diagnosis could be substantiated, and a period of observation was allowed during which 500 ml. of 10% dextrose solution was given intravenously. Six hours later the patient's temperature was 98.8°F and pulse-rate 84. There was no other significant alteration; but, since the tenderness in the right iliac fossa persisted the patient was operated on.

Laparotomy was performed twelve hours after admission. A McBurney incision was made and extended by cutting the muscle upwards. When the peritoneum was opened, a little free pus was found. The appendix was in an advanced stage of inflammation but had not ruptured; it was lying in the pelvic position. Appendicectomy was done, the stump was buried, and the abdomen was closed in layers without drainage.

Postoperatively morphine was given and the patient's condition was good for the first day. After forty-eight hours she became distended and began to vomit, and paralytic ileus developed. Streptomycin was given, and gastric suction and intravenous therapy without bowel stimulation was continued for four days before peristalsis started again satisfactorily. Thereafter the patient's recovery was uninterrupted.

Labour began spontaneously thirteen days after the operation. The uterine action was somewhat inert, but the patient delivered herself, with the aid of an episiotomy, of a baby weighing 8 lb. 3 oz. The wound healed satisfactorily.

Case 4.—A primigravida, aged 29, was admitted to hospital, when twenty-nine weeks pregnant, with two weeks' history of a "cold" in the course of which she developed pain in the right loin, made worse by walking, and this pain persisted after the cold had disappeared. Four days before admission she complained of sharp pain in the right groin which made her vomit, and this continued up to the time of admission. No record was available of her temperature during this time.

On examination her temperature was 96.8°F, pulse-rate 110, and tongue dry and furred. Tenderness was greatest in the right iliac fossa. A catheter specimen of urine showed no abnormality, and acute appendicitis with peritonitis was diagnosed.

Laparotomy was undertaken through an extended gridiron incision. Much pus was found in the peritoneal cavity. The appendix was retrocæcal and acutely inflamed but not ruptured. Appendicectomy was done, the stump was oversewn, a stab drain was inserted laterally, and the abdomen was closed in layers. Penicillin powder was dusted into the wound, and therapy with systemic penicillin and soluble sulphathiazole was begun immediately. Intravenous therapy was also begun at once, no fluid being given by mouth.

Labour.—Thirty-two hours after the operation labour began spontaneously, and after four hours low-forceps delivery was done under local infiltration anaesthesia; the baby was alive but premature and died soon after birth. No flatus was passed, and no gut sounds were heard for two days after the operation; but on the third day, when intravenous fluids were still being given, peristalsis began and the patient began to pass large liquid stools. She continued to have several loose motions daily for a few days. On the fourth day after operation her hæmoglobin was 36% and red cells 2,430,000 per c.mm. Altogether two pints of blood was therefore given on the fifth and sixth days, with considerable symptomatic improvement. The wound healed well, and the following year the patient had a normal pregnancy and delivery.

Case 5.—A woman, aged 31, was admitted at the thirty-sixth week of her fourth pregnancy. Throughout the pregnancy

she had not felt well. Six weeks before admission she complained of right-sided abdominal pain, shivering, sickness, and frequency of micturition. She was confined to bed for three weeks and was attended by her doctor; after this the pain became intermittent and less severe. Thirty-six hours before admission she had acute right-sided abdominal pain and vomited once. The pain persisted during the next day, and she vomited again. She began to want to pass water every few minutes and felt feverish. She was then admitted to hospital.

On examination she looked toxic, and her temperature was 99.8°F, pulse-rate 120, and tongue furred and dry. Her uterus was enlarged to the size of a full-term pregnancy, contracting strongly but relaxing normally between contractions. The fetal heart was heard. There was tenderness on pressure over the right side at the level of the umbilicus, and the patient noticed similar pain when the fetus moved. There was neither rigidity nor release tenderness, but there was slight tenderness on pressure over the right costovertebral angle. On vaginal examination no tenderness was felt and the cervix was not dilated. A catheter specimen of urine showed only an occasional pus cell but much acetone. The diagnosis seemed to rest between acute appendicitis and a relapsing pyelitis. It was decided to wait for a short time during which intravenous fluids and morphine were to be given. Four hours later the pulse-rate was 92, and after a further five hours the patient was feeling better and the pain was less. Her temperature was then 99°F and pulse-rate 112. Twelve hours after admission her temperature was 98.4°F and pulse-rate 100. She had had 2 litres of dextrose, 1 containing saline solution, and there was no acetone in her urine. She had vomited a few ounces of clear fluid, however, and there was tenderness on the right side of her abdomen at the level of the umbilicus.

Laparotomy was therefore undertaken, forty-eight hours after the onset of symptoms, through a McBurney incision extended by cutting the muscle. Free purulent fluid was present in the peritoneal cavity, and the inflamed appendix was found crossing the pelvic brim and burying its tip in the back of the broad ligament. The tip was firmly adherent and was separated only with difficulty. The fallopian tube and ovary were drawn down to this inflammatory zone. Appendicectomy was done, and the stump was buried. Penicillin powder 5 g. was placed in the peritoneal cavity, and the pelvis was drained through a rubber tube brought out through the lower end of the wound. The abdomen was closed in layers.

Postoperatively the patient became cyanosed whenever the administration of oxygen was stopped; so it was necessary to continue giving oxygen on her return to the ward. Treatment with intravenous fluids and large doses of penicillin and streptomycin was begun. Next morning the patient still tended to be cyanosed and was dyspnoeic at rest, though the lung bases were clear. That day routine investigation of her blood chemistry revealed considerable methemoglobinæmia. An intravenous injection of 10 ml. of methylene-blue solution improved her colour without entirely relieving her cyanosis. Occasional bowel sounds were heard; but there was considerable distension, and the stomach contents were therefore aspirated with a Ryle's tube left in situ. She received a mixture of Darrow's solution, Hartmann's solution, and 5% dextrose intravenously; and her general condition improved next day, although the ileus remained.

Labour.—Forty-eight hours after operation, with very little warning, she delivered herself of a healthy baby weighing 6 lb. 9 oz. Thereafter her pulse-rate improved, dyspnoea ceased, and tendency to cyanosis disappeared. The ileus was suddenly relieved on the third day, and she began to pass a large amount of liquid stools, after which the bowel returned to normal. The peritoneal drain allowed a large volume of serous fluid to escape, and this continued for some days after its removal. An alarm was raised that this contained a gas-forming organism, and anti-gas-gangrene serum was given; but her convalescence proceeded satisfactorily, and she was discharged after sixteen days. When she was seen as an outpatient, her wound had healed well and the baby was progressing satisfactorily.

This patient's breathing was considerably embarrassed by the combination of ileus secondary to peritonitis and a full-term uterus inhibiting movement of the diaphragm. If she had not gone into labour spontaneously, rupture of the membranes might have been justified to provide relief. The improvement after delivery was dramatic.

Case 6.—A woman, aged 25, was admitted, in the thirty-ninth week of her second pregnancy, with seven days' history of epigastric pain continuing until eighteen hours before her arrival in hospital, when it shifted to the right side and became spasmodic and severe. She had been vomiting for five days, and shoulder pain had arisen twelve hours before her admission. She was unmarried and had neglected to inform her doctor of her pregnancy and her illness alike.

On examination her temperature was 98.8°F, pulse-rate 110, and tongue dry and coated. Her abdomen showed generalised tenderness, maximal on the right side. Her abdominal wall was tense but not rigid. There was no release tenderness. The uterus was enlarged to the size of a full-term pregnancy, and the fetal heart was heard. On rectal examination there was no undue tenderness. A catheter specimen of urine showed no pus cells. Acute appendicitis was diagnosed.

Laparotomy was done through a right paramedian incision. Pus was found in the right paracolic gutter, and free fluid in the abdominal cavity. The appendix was found perforated, lying coiled behind the ascending colon. On dissection it broke off at its base, and the base could not be ligated. The patient's condition was then very poor. A stab-drain was made in the loin and the wound was closed, but she died undelivered six hours after operation. Cæsarean section post mortem produced a stillbirth.

Necropsy Findings.—Fibrinous exudate was present in the peritoneal cavity, causing adhesions between loops of bowel and occasional pockets of pus on the right side; the fibrinous exudate extended to the liver and diaphragm. In the cæcum there was a ragged abscess cavity, mostly retrocæcal and confined to the exterior of the bowel.

Diagnosis

HISTORY

2 patients gave a history of previous bouts of pain in which appendicitis was suspected, and this may be a valuable hint, as noted by Kerr and Moir (1949). The pain was typical of appendicitis (starting in the midline and soon settling in the right iliac fossa) in only 2 cases. In the other cases it could not be well localised by the patient and was described as "right-sided" or "lower abdominal." 1 patient noted pain on foetal movement. Vomiting at, or soon after, the onset of the pain occurred in all but 1 case (case 2), in which the history was deceptively trivial. Rigors did not occur in any case, but 2 patients (cases 4 and 6) described symptoms lasting two and six weeks and suggesting infection of the urinary tract, and it was particularly difficult on first examination to reach a correct diagnosis in these cases.

EXAMINATION

The temperature on admission ranged from 96.8° to 100°F and bore no relationship to the severity of the condition within the abdomen. The pulse-rate provided a better indicator, being less than 100 in patients with less than twenty-four hours' symptoms. The tongue also proved to be a reliable index of the patient's general condition, being coated in all the cases and moist only in the early admission. The abdomen is never easy to examine in these cases with a pregnancy near term. Krieg (1949) states that examination often shows an "interesting lack of findings." I prefer to emphasise the uncertainty of the physical signs compared with the clear-cut clinical findings of typical appendicitis in the non-pregnant patient.

Tenderness was present in all the cases, sometimes extending to the right hypochondrium and across to the left iliac fossa, but always maximal in the right iliac fossa or in the right para-umbilical area. It was never confined to a "point," and a confirmatory examination after an interval was often necessary to make certain that the right iliac fossa was the main source of trouble. In seeking to localise the site of abdominal tenderness, it should be recalled that the appendix is displaced upwards and outwards towards the flank as pregnancy advances (Baer et al. 1932). On occasion it was difficult to decide whether the source of the tenderness was

uterine or extra-uterine—e.g., in case 2. Only twice was guarding or rigidity noted, and release tenderness was not certainly defined in any case. *Vaginal and rectal* examinations were not helpful. This is what might be expected, because the depth of the pouch of Douglas is reduced in late pregnancy, and its contents are displaced upwards by the fetal head.

Auxiliary investigations have not been widely used in these cases. Krieg (1949) points out that a white-cell count is never pathognomonic and may be misleading—a third of his patients had counts of less than 14,000 per c.mm.—but a high count may confirm a presumptive diagnosis of appendicitis. A catheter specimen of urine should always be examined; but, since a clear specimen does not exclude pyelitis in pregnancy, and a small number of pus cells does not inculpate the renal pelvis, the only positive help comes from specimens which show a massive urinary infection.

DIFFERENTIAL DIAGNOSIS

Only two conditions were considered as alternative diagnoses in these cases. In case 2, where the tenderness was at first thought to be referred to the uterine wall, a small concealed accidental hæmorrhage was considered, but subsequent examination suggested an extra-uterine source of inflammatory nature, a suspicion which was supported by a slight rise in temperature and a raised white-cell count. In cases 2, 3, and 5 pyelitis was considered as a possible or probable diagnosis on first examination, but in all the cases appendicitis was suspected. In these cases delays of twelve hours occurred before laparotomy; in each case rest in bed and the use of sedatives produced a dangerously misleading improvement within four hours, and further periods of observation were allowed. In the absence of *positive* evidence of pyelitis after four hours this was probably an error of judgment. In case 4 the general practitioner was similarly misled to believe in a urinary cause for pain, and a rather longer delay resulted. Baird (1935) holds that in such cases a ureteric catheter should be passed, since this would relieve pain of renal origin. Other and rarer conditions may easily be confused with appendicitis. Child and Douglas (1944) and Priddle and Hesseltine (1951) list several such sources of error in their series (degenerating myoma, salpingitis, torsion of cyst. &c.).

Thus the early diagnosis of appendicitis in pregnancy must be made on relatively few clinical findings. The history may simply be that of abdominal pain, usually accompanied by vomiting and without rigors. On examination the patient is pyrexial but the temperature is commonly not much raised (100°F or less), the tongue is coated, and there is right-sided abdominal tenderness not well localised. There are no other reliable signs, and auxiliary investigations are disappointing. The condition most commonly confused with it is acute pyelitis. Probably in most cases of pyelitis severe enough to cause pain and vomiting a high temperature and pulse-rate will be recorded, whereas patients with low-grade pyrexia will rarely complain of abdominal pain. Unless there is a temperature of 101°F or more, with a history of rigors and with frank pus in the urine, it is dangerous to ascribe right-sided tenderness to pyelitis; for, as emphasised by all writers since Babler (1908), delay in the treatment of appendicitis in pregnancy is a most serious mistake.

Treatment

On studying the *management* of these 6 cases the most striking fact which emerges is the difference between the cases subjected to appendicectomy early (cases 1 and 2) and those (cases 4, 5, and 6) in whom operation was delayed forty-eight hours or more after the onset of symptoms. The former made a smooth recovery, whereas the latter had a stormy and worrying postoperative

course due to peritonitis and ileus. At laparotomy the best exposure in late pregnancy has been obtained through a high McBurney incision, starting in the plane of the anterior superior iliac spines and extending it upwards by cutting the muscle in the direction of the right loin.

In no case was the appendiceal infection localised. Many previous workers have commented on this and offered explanations—e.g., Warfield (1950). The main responsible factors appear to be the upward displacement which the appendix undergoes in pregnancy, the barrier placed in the way of the protecting omentum by the enlarged uterus, and the mobility of the inflamed zone due to the large contractile organ in close relation to it. In all the cases the general peritoneal cavity contained free fluid, fibrinous adhesions, or free pus. The appendix was not found in any constant position. A stab or wound drain was used in those cases where the appendix was ruptured, or where free purulent fluid was present in considerable amount. Antibiotics were used in all the cases, though it may be unnecessary in the early cases. It is a recurring fear of previous workers that the effect of labour will be to disseminate intra-peritoneal infection—indeed caesarean section has been advocated to avoid this (Crossen and Crossen 1948)—therefore every patient received antibiotics. In this series there was no evidence that *labour* following appendicectomy caused any such deterioration. 3 of the 5 patients who survived went into labour within forty-eight hours of operation. In all of these cases labour was uneventful; forceps delivery was undertaken when practicable to prevent maternal distress and to relieve strain upon the abdominal wound, but in all the cases healing of the wound was satisfactory, and any anxieties we felt were, in retrospect, largely unwarranted. Other workers—e.g., Meiling (1947)—have commented on the onset of premature labour following appendicectomy, and it seems that the onset of labour may be expected within forty-eight hours of operation in a good number of these patients near term.

The *baby* was unaffected by the mother's illness except in case 2, where the stillbirth remains unexplained. De Voe et al. (1947), discussing a similar intra-uterine death, suggest severe maternal acidosis as a factor, but in the present case the patient's general condition was good.

The *postoperative* course was uneventful in cases 1 and 2. In the cases subjected to laparotomy after a

TABLE I—HISTORY

Case no. and year of operation	Age (yr.)	Gravida	Gestation (weeks)	Symptoms			Duration on admission (hr.)
				Location of pain	Vomiting	Other

6	98.8	110	Coated, dry	+ Maximal in right iliac fossa	Nil	Nil	No pus	Not done

delay of more than twenty-four hours ileus secondary to peritonitis caused anxiety but responded finally to antibiotics, gastric aspiration, and intravenous replacement therapy biochemically controlled.

The clinical findings are summarised in tables I-III.

Discussion

The incidence of acute appendicitis in pregnancy is estimated to be about 1 in 1000-2000 cases (Baer et al. 1932, Child and Douglas 1944, Priddle and Hesseltine 1951), but it is probably higher than some workers suggest whose figures are taken from institutions dealing with obstetrics and gynaecology only. There seems to be no good reason to believe that the occurrence of appendicitis should be altered by the existence of a pregnancy (Johnson 1944). On the other hand, it is widely held that a patient subject to recurrent attacks of appendicitis is more liable to have an exacerbation during a pregnancy. The incidence of appendicitis in the different trimesters of pregnancy is assessed variously by different workers. The incidence is the same in the different trimesters in the series of Priddle and Hesseltine (1951) and Hoffman and Suzuki (1949), but most of the recent writers suggest that acute appendicitis is rarer in the last trimester (Child and Douglas 1944, Krieg 1949, Meiling 1947). No really satisfactory explanation for this has yet been offered. The most telling comment is that of Child and Douglas, who, noting the difficulty of diagnosis in a patient near term and the "natural hesitancy of obstetricians and surgeons to complicate a term pregnancy by an operation," suggest that appendicitis may be no less common in late pregnancy, but that an undue number may be given the opportunity of subsiding spontaneously. Thus, they infer, some patients will remain at home with their pain attributed to degeneration in a fibroid or to a small accidental haemorrhage, and will recover spontaneously. Others, diagnosed as having pyelitis, may receive chemotherapy and have their appendicitis cured. But some such patients will develop true obstructive appendicitis and require subsequent admission to hospital. If this be true, one would expect fewer admissions in the last trimester but a higher mortality-rate, because of the inclusion of these late or neglected cases. Reference to table IV appears to confirm this deduction.

In the present series, in relation to the question of misdiagnosis, it is reasonable to speculate whether the history of pyelitis preceding the acute phase of symptoms in cases 4 and 5 might not have been confused with that of subacute non-obstructive appendicitis. In fact I consider that many cases of appendicitis in pregnancy may be treated (sometimes successfully) as pyelitis with sulpha drugs and antibiotics, especially in the later months; and I believe that a reasonable suspicion of acute appendicitis at any stage of pregnancy should lead to laparotomy without delay. It will be seen that our

TABLE IV—PUBLISHED CASES OF ACUTE APPENDICITIS IN PREGNANCY

own practice has fallen short of this precept (cases 2, 3, and 5), yet a delay of more than four hours has seldom given any valuable information, and in retrospect I feel that further hesitation was unjustifiable in these cases (except perhaps in the very early admission, case 2).

At laparotomy, if appendicitis is confirmed, appendicectomy should be done without further interference. Though this opinion is now held by most workers, some (Meiling 1947, Potter and Sadugor 1949, Renn et al. 1951) have reported cases in the last trimester in which

TABLE III—TREATMENT

6	7 days	Necrotic at base, abscess around	Stab drain in loin	Died	Stillborn

appendicectomy was successfully combined with caesarean section. I suspect that the danger of peritonitis spreading after appendicectomy, owing to the presence of a contractile uterus, is a theoretical risk not borne out in practice today, and it certainly does not warrant routine opening of the uterus in the presence of known peritoneal sepsis. Where labour is imminent or in progress at the time of appendicectomy, and where an absolute barrier to vaginal delivery exists, the combined procedure will be necessary; it is in such cases that Kerr and Moir (1949) suggest that appendicectomy might be combined with caesarean section followed by total hysterectomy to provide drainage. In these circumstances, I think, hysterectomy should not be necessary, provided that antibacterial agents are freely available, but experience of such cases must obviously be very limited.

The objection may rightly be made that unnecessary laparotomies will be done as a result of these recommendations. In both the series of cases recorded by Child and Douglas (1944) and Priddle and Hesselstine (1951) 41 patients were subjected to laparotomy with a diagnosis of acute appendicitis. The diagnosis proved correct in only 25 and 28 cases respectively, but other conditions warranting laparotomy (ectopic pregnancy, twisted ovarian cyst, &c.) were found, and in only 5 cases in each series (of pyelitis or gastro-enteritis) was the laparotomy a mistake. In the four years during which the 6 cases reported here were treated at the Birmingham Maternity Hospital, 1 laparotomy was done in a case of pyelitis because appendicitis was suspected. It is admitted that, if appendicitis is to be treated early, as it must be in pregnancy, an occasional laparotomy will be done in error, but this seems a small price to pay for a handsome reward.

In assessing the results of the treatment of appendicitis in pregnancy today it is difficult to arrive at a figure representative of an over-all mortality. Meiling (1947) cites a maternal mortality-rate of 0.71% when disease is limited to the appendix, rising to 30% when peritonitis develops, and 50% after rupture of the appendix, and it is said that the rate is about 25% during the last trimester. These figures are probably dated, and in an effort to make an estimate in keeping with modern conditions table iv was compiled from series of 5 or more cases published in America in the last twenty years. Cases of true acute appendicitis only are included, and I believe that there is no overlapping between the series. Although no statistical reliance should be placed on figures from these obviously selected cases, an over-all mortality-rate of 5% may not be unfair for present-day conditions, and I submit that a mortality-rate for the last trimester ten times as high as that in the first six months proves conclusively the danger of the condition reported here.

Summary

6 cases of acute appendicitis complicating late pregnancy are described. 1 mother and 3 babies were lost.

The criteria of diagnosis are discussed with the object of minimising the delay in doing a laparotomy; in late pregnancy abdominal pain and vomiting with poorly localised right-sided tenderness and low-grade pyrexia means appendicitis until proved otherwise.

Appendicectomy without interference with the pregnancy through a high McBurney incision is advocated.

Labour tends to follow soon after operation, but no ill effects of this have been observed.

The mortality of appendicitis in late pregnancy is believed to be ten times as great as that in the early months, and possible reasons for this are discussed.

I wish to thank members of the consultant staff of the Birmingham Maternity Hospital for permission to publish case-records; especially Prof. H. C. McLaren, under whose care cases 2 and 5 (whom I treated) were admitted, and

Mr. A. L. Deacon, F.R.C.S.E., who operated on cases 3 and 4 and gave me much valuable advice in the preparation of this paper.

PROTECTIVE ANTIGEN OF HÆMOPHILUS PERTUSSIS

LOUIS PILLEMER

Ph.D. Western Reserve

PROFESSOR OF BIOCHEMISTRY

LIVIA BLUM

RESEARCH ASSOCIATE

IRWIN H. LEPOW

Ph.D. Western Reserve

ASSISTANT PROFESSOR OF BIOCHEMISTRY

WESTERN RESERVE UNIVERSITY, CLEVELAND, OHIO, U.S.A.

IN a preliminary report (Pillemer 1950) it was shown that an antigen (p.a.) could be extracted from *Hæmophilus pertussis* by sonic disintegration, and that it combined irreversibly under special conditions with human red-cell stromata. The stromata-protective antigen complex (s.p.a.) was shown to be a highly protective agent, judged by its ability to protect mice against intracerebral infection with *H. pertussis*, to be free from pertussis toxin, and to represent only a minute proportion of the organism.

We describe here investigations of the factors which influence the liberation of p.a. from *H. pertussis*, and of the conditions required for the interaction of p.a. with stromata. As a result of these investigations a method was devised for the large-scale preparation of s.p.a. for use in clinical trials.

Materials and Methods

H. pertussis Suspensions

A strain of *H. pertussis* designated 134 was used. The strain had been maintained in the vacuum-dried state. Other strains have also proved satisfactory, but most of the present work was done with no. 134, which proved amenable to sonic disintegration and produced little or no hæmagglutinin. Moreover, whole bacterial vaccines prepared from strain 134 protected mice against experimental intracerebral infection with *H. pertussis*.

In preparing suspensions for sonic treatment the following procedure was adopted:

The strain was cultured at 34°-36°C on Bordet-Gengou medium containing 30% sheep blood, and the 24-48 hr. growth was inoculated into flasks of modified Cohen and Wheeler (1946) medium made with a specially prepared human peptone (supplied by Lederle Laboratories). The flasks were incubated at 34°-36°C for about 40 hr. with gentle agitation, during which time the total bacterial count increased from

Fig. 1—Protective potency of S.P.A. prepared from 500×10^9 organisms per ml. subjected to sonic treatment for different lengths of time. In figs. 1-5 the protective potency is given as a percentage of the potency of the parent bacterial suspension.

about 1×10^9 per ml. to about 50×10^9 organisms per ml. (U.S. National Institutes of Health opacity standard). The bacteria were separated from the culture and washed with distilled water at 1°C and then stored at $2^\circ\text{--}5^\circ\text{C}$ for no longer than 24 hr. before resuspension and sonic disintegration. The deposit was suspended in distilled water to give a concentration of about 500×10^9 organisms per ml. Throughout these operations sterile precautions were observed, since it was impossible to sterilise S.P.A. by filtration.

Stromata

Group-O Rh-negative erythrocytes were washed four times with 5 volumes of 0.15 M sodium chloride at 1°C and then lysed by adding 10 volumes of cold distilled water to 1 volume of packed cells, adjusting the pH value of the mixture to 5.2-5.4 with acetic acid, and allowing it to stand overnight at 1°C . The stromata were then centrifuged at 1°C for 1 hr. at 4000 r.p.m. and washed three times with 20 volumes of cold distilled water. A 50% suspension was prepared from the deposited stromata by suspending them in water to twice the volume which the washed packed cells originally occupied. This suspension was autoclaved at 15 lb. for 30 min.

Sonic Oscillators

Two types of sonic oscillator, manufactured by the Raytheon Manufacturing Company, Waltham, Massachusetts, U.S.A., were used: type R-22-1 (10 kilocycles, 200 watts) and type R-23-3 (9 kilocycles, 60 watts). The former type proved the more successful since it could deal with larger volumes and was more efficient in liberating P.A. The vibrator-cup assembly was autoclaved at 15 lb. for 30 min. and then filled with the bacterial suspension, which was maintained at 1°C during sonic treatment.

Fig. 2—Protective potency of S.P.A. prepared by interaction of P.A. and stromata for different lengths of time; other conditions constant.

Assessment of Protective Potency

The protective potency of the various preparations was tested by immunising mice and determining the level of immunity by intracerebral challenge of virulent *H. pertussis* (Kendrick et al. 1947). All the preparations were diluted before testing so that they contained the equivalent of 10×10^9 organisms per ml. It was thus possible to compare their protective action directly with that of the parent bacterial suspension made up to a concentration of 10×10^9 organisms per ml. and to express their potency as a percentage of the potency of the bacterial suspension (figs. 1-5).

In assessing the potency of S.P.A. prepared for clinical trials at least three tests were made on samples from each batch by the method suggested by the United States National Institutes of Health (1952) using their reference pertussis vaccine.

Experimental

PREPARATION OF SONIC EXTRACTS

It was found that the amount of P.A. liberated from the organisms depended on the volume of the suspension, the type of oscillator, the temperature, and the time of sonic treatment. Optimal conditions were obtained with Raytheon oscillator type R-22-1, when 60 ml. of an aqueous bacterial suspension containing 500×10^9

Fig. 3—Protective potency of S.P.A. prepared by interaction of P.A. and stromata at different pH values; other conditions constant.

organisms per ml. was subjected to sonic disintegration at 1°C for 30 min., or 130 ml. for 2 hr. The Raytheon type R-22-3 was not so effective (fig. 1). These optimal conditions for the production of P.A. relate entirely to strain 134; if other strains are used, the optimal conditions may be different.

After sonic treatment 1 part of Eagle's solution (sodium chloride 17.0 g., potassium dihydrogen phosphate 1.36 g., sodium hydroxide 0.35 g., distilled water 100 ml.; pH 7.35 ± 0.05) was added to 19 parts of the disintegrated suspension maintained at 1°C , giving an ionic strength of 0.15 and a pH value of 7.05 ± 0.05 . The suspension was left at 1°C for 12-24 hr., and the insoluble residue was removed by centrifugation at 1°C for 2 hr. at 4000 r.p.m. The precise control of pH at this stage was important because a reduction of the pH value below 6.8 led to the precipitation of P.A. with the insoluble residue.

INTERACTION OF P.A. WITH STROMATA

Experiments were made to determine the ideal conditions for the combination of P.A. with stromata. Clarified sonic extract was mixed with 50% autoclaved stromata in different proportions at different ionic concentrations, pH values, and periods of incubation of the mixture. Incubation was at 37°C because experiments showed that at this temperature the combination of P.A. and stromata was complete in about 1 hr. (fig. 2). After incubation the mixtures were centrifuged at 4000 r.p.m.

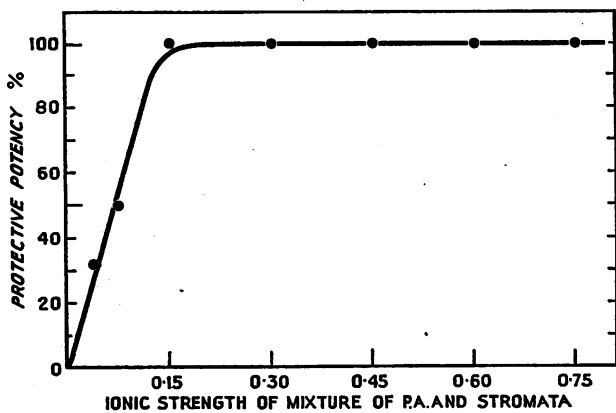

Fig. 4—Protective potency of S.P.A. prepared by interaction of P.A. and stromata at different ionic strengths; other conditions constant.

at 1°C for 1–2 hr. The supernatant fluids were discarded, and the residues were suspended uniformly to the desired concentration in glycine-phosphate buffer at pH 7.4 (9 parts of 0.3 M glycine and 1 part of M/15 phosphate buffer) containing 1/10,000 thiomersalate.

The results of some of the experiments are summarised in figs. 3–5, from which the following conclusions were drawn:

(1) P.A. combined with stromata at pH 6.85 ± 0.05 and slight deviations from this pH produced a less potent preparation of S.P.A. (fig. 3).

(2) P.A. combined with stromata at an ionic strength of 0.15 or more, and ionic strengths less than 0.15 retarded combination (fig. 4).

(3) The most active preparations of S.P.A. were obtained when 30 parts or less of P.A. were added to 1 part of 50% stromata suspension (fig. 5).

LARGE-SCALE PREPARATION OF S.P.A.

As a result of these experiments the following procedure was decided on for the large-scale preparation of S.P.A. We consider that this procedure should be rigidly followed to obtain reproducible results, since slight deviations, which may seem insignificant, cause a decrease in the yield, purity, and antigenic potency of the final product.

(1) The growth of *H. pertussis* in modified Cohen and Wheeler medium was centrifuged at 4000 r.p.m. for 1 hr. at 1°C.

(2) The deposit was washed five times with large volumes of distilled water at 1°C.

(3) The washed bacteria were suspended to 500 × 10⁹ organisms per ml. in distilled water at 1°C.

(4) The suspension in 60 ml. amounts was subjected to disintegration at 1° ± 1°C in the Raytheon type R-22-1 sonic oscillator for 40 min., or in 130 ml. amounts for 2 hr.

Fig. 5—Protective potency of S.P.A. prepared by interaction of different proportions of stromata and extract; other conditions constant.

(5) To 19 parts of sonic disintegrated suspension 1 part of Eagle's buffer solution was added, and the final pH was adjusted, if necessary, to 7.05 ± 0.05.

(6) The buffered disintegrated suspension was allowed to stand overnight at 1°C and then centrifuged at 1°C for 2 hr. at 4000 r.p.m. The deposit was discarded.

(7) To 30 parts of clear extract at pH 6.85 ± 0.05, 1 part of 50% autoclaved stromata suspension was added, and the mixture was incubated in a water-bath at 37°C for 2 hr.

(8) The stromata-extract mixture was centrifuged at 1°C for 2 hr. at 4000 r.p.m. The supernatant fluid was discarded.

(9) The deposited S.P.A. was suspended in glycine-phosphate buffer at pH 7.4 containing 1/10,000 thiomersalate.

(10) The suspended S.P.A. in 100 ml. amounts was subjected to sonic vibration at 1° ± 1°C in the Raytheon type R-22-1 sonic oscillator for 30 min. to produce a homogeneous suspension.

PROPERTIES OF LARGE-SCALE PREPARATIONS OF S.P.A.

This procedure yielded stable and sterile preparations of S.P.A. which protected mice against intracerebral infection with *H. pertussis*. Typical protocols are given in the accompanying table of tests made on two different

COMPARISON OF PROTECTIVE ACTION OF 2 BATCHES OF S.P.A. WITH U.S. NATIONAL INSTITUTE OF HEALTH REFERENCE VACCINE N.I.H.4

Preparation	Dose inoculated (ml.)	Proportion of mice surviving after challenge
S.P.A. (batch 51200-35)*	1/21	54/63
	1/105	29/64
	1/525	15/64

	1/525	5/32
N.I.H.4	1/6.7	24/32
	1/33.5	8/32
	1/167.5	5/32

* Equivalent to 100 × 10⁹ organisms per ml.

batches of S.P.A. in comparison with the National Institutes of Health reference vaccine. These batches were made up equivalent to 100 × 10⁹ organisms per ml., and the results indicated that each batch was from four to six times as potent as the reference vaccine.

Tests made with S.P.A. heated at 56°C for 1 hr. indicated that such treatment did not reduce the protective potency. Other experiments showed that S.P.A. remained stable for fifteen months at 1°C and for six months at 37°C, although it was readily inactivated at 100°C.

S.P.A. was shown to be non-toxic. The intravenous injection of 1 ml. of S.P.A. made up equivalent to 250 × 10⁹ bacteria was tolerated by mice and by guinea-pigs, and 5 ml. by rabbits, without showing any harmful effects.

No attempts were made to characterise S.P.A. completely. Electrophoretic analyses of extracts before and after addition of stromata showed no alteration in the distribution or mobilities of the electrophoretic components, and no difference was detected in the nitrogen content of extracts before and after addition of stromata. These observations indicate that P.A. represented only a minute proportion of the organism, probably less than 1% of the nitrogenous material in the extract.

Discussion

Although the nature of P.A. is not yet known, certain information about its properties is evident. It appears to be firmly associated with the bacterial cell and not loosely attached to the cell surface. Bacteria which were washed many times before they were subjected to sonic disintegration yielded high concentrations of P.A. The

extraction of P.A. from the cell by sonic disintegration and separation from the extract by stromata was largely quantitative; for under optimal conditions the protective potency of S.P.A. was very similar to that of the parent bacterial suspension. P.A. is probably not associated with pertussis hæmagglutinin (Keogh and North 1948), since this latter antigen does not protect mice against intracerebral infection (Masry 1952). Moreover the strain used produced only small amounts of hæmagglutinin, and this antigen has not been detected in preparations of S.P.A. It is also evident that P.A. is not associated with pertussis toxin (Evans and Maitland 1937); preparations of S.P.A. were unable to kill mice on intravenous injection or to produce dermonecrosis in rabbits. Finally, P.A. is not associated with pertussis agglutigen. D. G. Evans and F. T. Perkins (private communication) have recently shown that S.P.A., tested by the agglutinin-production method (Evans and Perkins 1953), produced little or no agglutinin in mice. Although there is little or no evidence of an association between P.A. and the other known antigens of *H. pertussis*, there is some evidence that P.A. may be concerned with the ability of the organism to sensitise mice to histamine. Margaret Pittman (private communication) has recently shown that S.P.A. produced in mice a sensitisation to histamine similar to that produced by whole bacterial vaccines. This is interesting because the power to render tissues sensitive to histamine and the protective potency of bacterial vaccines have been shown to be very closely correlated (Pittman 1951).

The question of the efficacy of S.P.A. as a prophylactic against whooping-cough can only be answered by controlled trials, which are now in progress. If such trials prove that S.P.A. is effective, a more extensive investigation of the nature of the antigen is undoubtedly justified.

Summary

An investigation was made of the factors which influence the liberation of a protective antigen (P.A.) from *H. pertussis*, and of the conditions required for the formation of a stromata-protective antigen complex (S.P.A.).

A method is outlined for the large-scale production of S.P.A. The method involves the extraction of P.A. from *H. pertussis* by sonic disintegration and the removal of P.A. from the extract by the addition, in suitable proportions, of autoclaved stromata under controlled conditions of temperature, pH, and ionic strength.

Preparations of S.P.A. prepared for clinical trials have been tested in comparison with the U.S. National Institutes of Health reference pertussis vaccine and shown to be effective in protecting mice against intracerebral infection with *H. pertussis*.

We are indebted to Dr. Margaret Pittman, of the National Institutes of Health, Bethesda, Maryland; Dr. Pearl L. Kendrick, of the School of Public Health, University of Michigan, Ann Arbor, Michigan; Dr. Grace Eldering, of the Michigan Department of Health, Grand Rapids, Michigan; Miss Frances L. Clapp and Miss Frances W. Bingham, of Lederle Laboratories, for conducting many mouse-protection tests; and to Dr. H. D. Piersma and Mr. W. S. Hammond, of Lederle Laboratories, for generous supplies of *H. pertussis* specially grown for this investigation, which was supported by a grant from Lederle Laboratories Division, American Cyanamid Company, Pearl River, New York.

CHRONIC SUBDURAL HÆMATOMA MENTAL CHANGE AS THE PRINCIPAL CLINICAL FEATURE

EDWIN CLARKE

M.B. Durh., M.D. Chicago, M.R.C.P.
ASSISTANT LECTURER IN NEUROLOGY

ROSEMARY COOPER
M.B. Camb., M.R.C.P.

LATE HOUSE-PHYSICIAN TO THE DEPARTMENT OF
MEDICINE (NEUROLOGY)
POSTGRADUATE MEDICAL SCHOOL OF LONDON AND
HAMMERSMITH HOSPITAL

It is well known that mental changes are often produced by a subdural hæmatoma, but when such changes occur in the absence of a history of trauma to the head, and when there are no abnormal neurological signs initially, the diagnosis of subdural hæmatoma is difficult.

Case-report

A publican, aged 59, was admitted to Hammersmith Hospital on Aug. 7, 1952, under the care of Dr. Purdon Martin. In the past he had suffered many minor ailments and had attended the hospital on several occasions for numerous vague symptoms. During the first world war, 34 years before admission, he had "shell shock" and as a result spent a year in hospital. During this time he complained of incessant headaches but made a satisfactory recovery. No further details of this illness could be obtained. Since then he had occasionally experienced headaches that were neither persistent nor severe. His wife said that, apart from being abnormally preoccupied with the state of his health, there had been no mental change in the past. He did not usually drink heavily, but recently he had been drinking more than usual. The family history contained no relevant information. Five weeks before admission he began to have headaches, and at first thought these were the same as he had experienced previously. A bifrontal ache with a sensation of pressure on the vertex was constantly present, occasionally disturbing sleep. Stooping sometimes aggravated it, but there was no nausea, vomiting, vertigo, or visual disturbance. A change of glasses gave no relief, and analgesics eased the pain only temporarily.

On examination his general condition was good, and despite his pale skin the blood picture was normal. He lay in bed with his eyes closed and gently rocked his head from side to side, giving an impression of intense suffering. He gained a great deal of sympathy from his fellow patients and he obviously enjoyed and sought this. He was alert and able to give an adequate history as well as cooperate in all the tests used. There was no defect of intellect or of memory, and his personality was unimpaired. The central nervous system was entirely normal. The blood-pressure was 140/90 mm. Hg, and his cardiovascular and other systems showed no abnormalities.

Investigations.—Radiographs of the skull and of the chest were normal. Cerebrospinal fluid (c.s.f.) under a pressure of 100 mm. of water contained 2 lymphocytes per c.mm., and protein 30 mg. per 100 ml. The Lange reaction was normal, and the Wassermann reaction was negative. The Wassermann reaction of the blood was also negative.

Progress.—In view of the complete lack of abnormal physical signs, the normal results of the investigations, and the patient's previous history, it was thought that his state was not due to an organic lesion of the nervous system. His wife was not unduly surprised at this conclusion, feeling that his present illness was "all in his mind" and probably related to recent business difficulties. He was therefore encouraged to get up, and for a few days the headaches seemed to subside. This, however, was only temporary, and soon he could not be coaxed from his bed. It was now evident that his mental state was changing. He became drowsy but could always readily be roused to cooperate fully. At times he was confused and disoriented. He talked incoherently and in a rambling fashion, with a tendency to perseverate. He exhibited amnesia and mild euphoria, at times displaying a childishness and fatuousness hitherto foreign to him. He would make bizarre facial grimaces and often muttered to himself. The headache was still present but did not seem to have become worse. At this time, and throughout the nineteen days that had elapsed since his admission, no abnormal signs were

detected in the central nervous system, despite careful and regular observation. A psychiatric opinion was then sought, and it was considered that he presented an organic syndrome characteristic of progressive cerebral deterioration. The diagnosis seemed to lie between a type of presenile dementia and chronic alcoholic deterioration. Admission to an observation ward was advised, and arrangements for this were being made when, on Aug. 29, 1952 (three weeks after admission), the patient suddenly developed an acute pulmonary infection. Three days later, while his chest condition was responding to treatment, his mental state had deteriorated further. He had periods of great restlessness, and satisfactory contact with him was impossible. He still complained of headache, but his speech was mostly incoherent and often incomprehensible. At times he was very drowsy but he could always be aroused without difficulty and he was never comatose nor incontinent. The c.s.f. pressure was so low that it could not be recorded; it was normal in content. Four days later, on Sept. 5 (thirty days after admission), abnormal neurological signs were detected for the first time. There was definite falling away of the right arm when both were outstretched, the reflexes were slightly increased on the right side, and both plantar reflexes were weakly extensor. Since he might have had a frontal neoplasm or possibly a subdural hæmatoma, he was transferred to a neurosurgical unit (Mr. Geoffrey Knight) where, on the same day, 30 ml. of old blood was evacuated from the subdural space on each side. It was thought that it had probably been present less than six months. He made a very rapid and gratifying recovery: a week after the operation he was free from all headache, bright and alert, and no longer confused or disorientated. In fact he was an entirely different person; instead of being dull and complaining he was now likeable and jovial. He now said that during his work he frequently had to pass beneath a low-beamed door and often knocked his head against the lintel. At no time, however, had he been rendered unconscious, and he did not recall any particularly severe blow before the onset of his headaches. Intellectual testing and assessment of his personality, as well as examination of his nervous system, revealed no abnormalities, and he was discharged on Oct. 13, 1952. When seen a year later, he had returned to his work and had no complaints at all.

Initially there was no history of head injury, and even on direct questioning after operation there was only a vague story of repeated trivial blows, reminiscent of Trotter's (1914) second patient in whom there was the same type of trauma to the head. Many years previously our patient had had a psychiatric illness which included severe headaches, and in the ensuing years had experienced many illnesses, some of which were without an organic basis. He was known to be anxious and hypochondriacal, and when headaches returned as the first manifestation of the subdural hæmatoma it was thought that they were functional. Despite repeated and careful examination no clinical abnormalities were found in the central nervous system, and the appropriate special investigations gave normal results. Only late in the illness did signs of focal cerebral involvement develop, and at no time was there any indication of increased intracranial pressure. After the subdural clots had been removed, the patient recovered completely.

Discussion

All writers agree that mental disturbances are among the most common manifestation of chronic subdural hæmatomas, yet this fact is rarely mentioned in textbooks on psychiatry. Admittedly, in most cases the symptoms and signs are sufficient to warrant a tentative diagnosis, but rarely is the clinical picture mainly psychiatric.

INCIDENCE OF MENTAL CHANGES

The incidence of mental changes has been assessed very differently by different writers, the more reliable figures being 21.2% of 48 cases (Kunkel and Dandy 1939), 75% of 50 cases (Krayenbühl and Noto 1949), 86% of 44 cases (Jelsma 1930), and in all of 50 cases (Wortis et al. 1945). Trotter (1914) emphasised the mental changes and believed that they occurred in many, if not all, cases of subdural hæmatoma. This notion was corroborated by Coleman (1935), who said that, in cases of

subdural clot, changes in mental state are found "perhaps oftener than in any space-occupying lesion of the brain."

The figures given by different authors depend partly on their conception of the term "mental changes" and partly on the thoroughness with which they are sought. Wortis et al. (1945) examined their cases very carefully and found mental changes in all of them. On the other hand, although we agree with Abbott et al. (1943) that psychiatric estimation is important in all cases of chronic subdural hæmatoma it is, in our view, by no means the major aspect of the clinical problem, as these workers would have us believe.

It is well known that there is a high incidence of subdural hæmatoma among inmates of mental institutions coming to necropsy. Allen et al. (1940) found 245 (7.9%) in 3100 consecutive necropsies on psychotics, exactly the percentage recorded by Lewis (1889). In only 35 of the cases of Allen et al. (1940), however, was the subdural hæmatoma the primary cause of death, and it was impossible to say in how many patients the psychosis was due to the subdural clot. That epileptics and alcoholics have a greater liability to head injuries, and that cerebral changes in arteriosclerotics and neurosyphilitics may predispose to subdural hæmatoma, is admitted by Allen et al., and such conditions are probably all-important in these cases.

Another cause to be considered is the form of therapy used. The schizophrenic reaction in Singh's (1950) patient may have been produced by a subdural hæmatoma precipitated by electroconvulsive therapy; and Furlow (1939) blames insulin-shock therapy in his case 2. These forms of therapy, however, seem to be less likely causes of subdural hæmatoma, which has not so far been reported as a complication of these widely used procedures. The reason why only certain patients with subdural hæmatomas manifest prominent mental changes is explained best by Lewis (1946): any disturbance of the brain, whether it be head injury, anæmia, toxic agents, or focal lesion, if severe enough, will interfere with the mental state and so produce a type of mental reaction typical of an organic lesion. But some people are more loosely integrated in their personality, being "oriented toward psychosis" (Lewis 1946); their past history may readily illustrate this; they break down mentally more readily and much more extensively under stress than the more intact person, and psychiatric features dominate the clinical picture.

TYPES OF MENTAL CHANGES

Wortis et al. (1945) have carefully analysed the mental disturbances in patients with acute or chronic subdural hæmatoma. They recognised that it was difficult to exclude other coexisting traumatic cerebral lesions that would complicate the clinical picture. However, in a series of 50 cases, they divided the preoperative mental changes into groups which included changes in the state of consciousness and in mood and disturbance of the sensorium and of thinking. They found that in each of their patients there was some mental abnormality. Like other workers, they included disordered states of consciousness which are present in all cases at one time or another and should perhaps be considered separately. The high incidence (86%) of mental changes in Jelsma's (1930) collected series, for example, is probably explained by the inclusion of drowsiness and the various stages of coma.

The commonest psychological findings of Wortis et al. (1945) were progressive confusion and disorientation (present in two-thirds of cases), emotional dullness, irritability, and uncoöperativeness (in a quarter of cases), and a general reduction in mentation. de Morsier (1937) mentioned a similar rather non-specific constellation of mental changes, which are often included in the term "dementia." Depression, euphoria, delirium, hallucina-

CASES OF CHRONIC SUBDURAL HÆMATOMA WITH MENTAL CHANGE AS PRINCIPAL CLINICAL FEATURE

Reference	Sex	Age (yr.)	Presenting symptoms	Mental features	Duration to operation or death	Findings at operation	Outcome
Trotter (1914) case 2	M	41	"Strange manner"	Absent-minded; lack of initiative	?	Left-sided hæmatoma	Complete recovery
Martin (1931) ..	M	52	Headaches	Vague; poor memory; repetitive	5-6 mos.	..	Death; hæmatoma not described in detail
Furlow (1936) case 8	M	45	Irritability, with suicidal tendencies	Poor memory; dis-oriented	10 mos.	..	Death; right-sided hæmatoma
Olkon (1938) ..	M	37	Acute confusional state	Paranoia; hallucinations and delusions	11 days (see text)	Dark subdural blood	Complete recovery
Furlow (1939) case 1	M	63	Mental changes	Dementia with sexual aberrations; irritable	3 yr.	Right-sided hæmatoma	Complete recovery
Furlow (1939) case 3	M	48	Headache and vomiting	Hallucinations	4 mos.	Right-sided chronic hæmatoma	Slow but complete recovery
Fleiss (1945) ..	M	56	Manic-depressive psychosis	..	2 mos. (see text)	Left-sided hæmatoma	Several relapses but eventual recovery
Whitfield (1946) case 1	M	32	"Peculiar behaviour"	Transient amnesia	7 yr. (see text)	Left frontal hæmatoma	Complete recovery
Clarke and Cooper	M	59	Headache	Confusion; disorientation; mental deterioration	2 mos.	Bilateral hæmatoma	Complete recovery

tions, and delusions, on the other hand, were rare. Confusion tends to be more severe in the older patients; and alterations in personality, particularly in the patient's attitude to his work and family, are important. Wortis et al. (1945) emphasised the diagnostic importance of the steady progression of mental deterioration—an event that was witnessed in the present case. Krayenbühl and Noto (1949) mentioned disorders of affect, lack of initiative and critical judgment, weakness, and apathy as common mental disturbances. Homburger (1905) described a patient with a Korsakoff type of psychosis produced by a subdural hæmatoma, and Kasemeyer's (1911) patient was thought to have a post-traumatic neurosis. Among the 50 cases of Krayenbühl and Noto (1949) there were 2 (cases 4 and 46) displaying features of a frontal-lobe lesion. There were also physical abnormalities present, and the cases reported by Petit-Dutaillis et al. (1953) were similar. The case of Mioheels (1953) is the only one in which a catatonic state was a prominent feature.

Thus, just as many neurological syndromes may be produced by a subdural collection of blood, so the psychiatric disorders are likewise variable, within the organic reaction pattern.

MENTAL CHANGES AS PRINCIPAL CLINICAL FEATURE

We are particularly concerned with cases of subdural hæmatoma in which mental disturbances and headache are the sole features of the early stages of the illness, there is no evidence of head injury, and the nervous system is normal.

Trotter (1914) stated: "These mental symptoms may be perceptible even to uneducated observers, when no physical signs of interference with the brain can be detected." Ample confirmation of this statement has been produced by different workers, particularly Wortis et al. (1945), who occasionally found patients in whom the mental abnormalities far outweighed the neurological abnormalities. At least 8 cases similar to ours have been published in which the principal clinical feature at the onset was an abnormal mental state, and the nervous system and special investigations were all normal. These cases are summarised in the accompanying table.

Other cases with predominant mental changes have been recorded, but in all of them a history of trauma was readily elicited or examination revealed neurological abnormalities indicating a focal cerebral lesion (Homburger 1905; Kasemeyer 1911; Furlow 1936, case 10; Linell 1940, cases 4 and 5; Abbott et al. 1943, case 7; Matera et al. 1948, 2 cases; Krayenbühl and Noto 1949, cases 4 and 46). It is important to remember these cases when dealing with postconcussional psychotic or neurotic

states, for if a subdural hæmatoma is left untreated it will almost always prove fatal; but if it is removed the results can be excellent. As mentioned already, however, the picture may be complicated by additional intracranial damage. This may have been so in case 4 of Linell (1940), where operation did not dispel the patient's mental symptoms.

Of the cases in the table mention must be made of 3. The patient of Fleiss (1945) had several manic and depressive episodes that usually coincided with the appearance of a subdural accumulation; but they did not always do so, and one cannot subscribe to Fleiss's suggestion that the clot may at times have been absorbed spontaneously. In Whitfield's (1946) first patient mental changes had been present seven years; but it is doubtful if the subdural clot was of a similar age; although recovery was complete after the removal of the hæmatoma, only further observation will determine the actual rôle of the mental features. The patient described by Singh (1950) presented with a schizophrenic reaction, and a subdural hæmatoma was found at necropsy. It was difficult, however, to correlate these two findings; as mentioned already, the possibility of the clot being a product of electroconvulsive therapy, although unlikely, could not be entirely excluded. Because of the uncertainty this case will not be considered further.

In summarising the clinical picture in the selected group of cases shown in the table, it is seen that all the patients were men. Since subdural hæmatoma occurs more often in males, this finding is of little significance in a small series. The ages varied from 32 to 63, the average being 49; if anything, there was grouping in middle and late adult life. So far as was known initially, there had been no injury to the head, although it transpired later that Trotter's (1914) second patient and ours had repeatedly sustained minor trauma. In case 8 of Furlow (1936) there was no history of head injury, but the patient was a chronic alcoholic, and radiographs and necropsy revealed skull fractures. Similarly, in Whitfield's (1946) patient, radiographs showed a fracture, although there had been no indication of trauma. The mental changes mentioned in the series were of considerable variety, no constant syndrome being observed. They usually began insidiously. In Olkon's (1938) patient the onset seemed to be acute, but it was later revealed that personality changes had preceded the acute exacerbation; the clot was found to be of long standing and therefore must have antedated the presenting confusional state. All the patients had headache, which usually began after the mental changes, and disturbances of consciousness were invariably present. The characteristic waxing and waning of consciousness was not

regularly seen but, if present, is a most helpful sign of subdural hæmatoma. The length of history varied from a few weeks to three years. Abnormal neurological signs were absent initially but appeared later in all the cases, usually accompanying the increasing drowsiness, as often happens in this condition. Apart from the drowsiness, signs of increased intracranial pressure were rare. Special investigations were of little diagnostic value. The c.s.f. was examined in 6 of the patients, and the pressure was either normal or less than normal in all of them; only 1 patient had xanthochromia, and he and another patient had an increased amount of protein in the c.s.f. Skull radiography was done in 6 cases, and, apart from the 2 patients with fractures mentioned already, they were always normal.

The preoperative diagnoses in these cases were acute psychosis, war neurosis, frontal tumour, cerebral degeneration, presenile dementia, and manic-depressive psychosis. All but 2 patients were operated on, and subdural hæmatomas of various sizes and in various positions were successfully removed. There seemed to be no correlation between the location and size of the lesion and the clinical picture, but full details of the clot were rarely available. Of the 9 cases in which mental change was the principal feature the hæmatoma was bilateral in the present case only.

Although the follow-up on most of these cases was limited and the end-results are thus unknown, the immediate postoperative recovery, both mental and physical, was rapid and usually complete. This fact emphasises the importance of being aware of this small group of cases. In any patient with severe headache who manifests progressive non-specific mental changes accompanied by increasing drowsiness, which may or may not fluctuate, a subdural hæmatoma should be considered, even in the absence of known trauma, increased intracranial tension, and abnormal neurological signs. If the drowsiness leads to coma, and abnormalities of the central nervous system appear, special diagnostic procedures and the help of a neurosurgeon are called for immediately.

Summary

A case of chronic subdural hæmatoma is described in which the major clinical feature was mental change without any history of head injury. The central nervous system appeared to be normal, as were skull radiographs and the c.s.f. Removal of the clot led to complete recovery.

The mental changes observed with subdural hæmatoma are described, and previously published cases are discussed.

We wish to thank Dr. Purdon Martin for permission to publish this case; Dr. Purdon Martin and Dr. Denis Hill for criticism and advice; and Mr. Geoffrey Knight, F.R.C.S., for help with this case.

HEPATIC COMA *

A. G. RIDDELL

From the Department of Surgery, Harvard Medical School, and the Surgical Service, Massachusetts General Hospital

A NEUROLOGICAL syndrome termed "episodic stupor" has been observed in patients who have undergone portacaval anastomosis. This syndrome has been shown to be caused by ammonia intoxication (McDermott and Adams 1954). The similarity of "episodic stupor" to hepatic coma is striking, since the neurological disturbances are similar to, and the electro-encephalographic changes identical with, those observed in patients with liver disease who are in a state of stupor or coma (Adams and Foley 1949, Foley et al. 1950).

Because of this similarity between episodic stupor resulting from a portacaval anastomosis and the syndrome of hepatic coma, we have investigated the ammonia metabolism of patients with liver disease. Other investigators have reported changes of the blood-ammonia level in liver disease (Burchi 1927, Caulaert et al. 1932, Fuld 1933, Kirk 1936, Gaustad 1949), but the results of their studies have been inconclusive and have not established ammonia as an aetiological factor in hepatic coma.

A syndrome indistinguishable from hepatic coma has been reported to follow the administration of an ammonium-containing cation-exchange resin to patients with cirrhosis of the liver (Gabuzda et al. 1952). Later Phillips et al. (1952) reported their findings in a group of 9 alcoholics with advanced cirrhosis who were given various nitrogenous substances. Five substances were given by mouth: ammonium chloride, diammonium citrate, an ammonium-potassium exchange resin, urea, and a high-protein diet. A condition resembling the onset of hepatic coma occurred in 5 of the 9 patients studied. The blood-ammonia levels were estimated, but the correlation between the blood-ammonia level and the abnormal signs was not consistent enough to establish a direct relationship.

Walshe (1951, 1953) suggests that hepatic coma may be due to an intracellular disturbance of ammonia metabolism, and that in hepatic coma the normal ammonia-binding mechanism of the brain-cell, the combination of glutamic acid with ammonia to form glutamine (Weil-Malherbe 1950), is disturbed. This theory is supported by the observation that glutamic-acid therapy led to the recovery of 3 patients who between them had five episodes of hepatic coma (Walshe 1953).

Fig. 1—Case I: pattern of blood-ammonia levels in hepatic coma precipitated by massive hæmorrhage from œsophageal varices.

* These studies were supported by grants from the Atomic Energy Commission and the U.S. Public Health Service, National Institutes of Health.

In our investigation the peripheral blood-ammonia levels were determined in patients with hepatic coma, and the effect of glutamic acid on both clinical symptoms and blood-ammonia levels was studied.

Methods

The patients were under observation in the wards of the Massachusetts General Hospital. They were seen daily, often more frequently, when their neurological status was assessed and their peripheral blood-ammonia levels were determined. None of the patients had undergone portacaval anastomosis.

To correlate the mental state and the biochemical findings, the degrees of alertness and reactivity were graded on a scale from 0 to 4. Normal mental function was recorded as 0, coma as 4, the slightest alteration of mental function as 1, severe mental confusion or disorientation as 2, and stupor and semicoma as 3.

The electro-encephalographic changes were graded from 0 to 3, zero meaning normal. This scheme of reporting the neurological and electro-encephalographic changes has already been published in detail (McDermott and Adams 1954).

Blood-ammonia levels were determined by a modification (McDermott and Adams 1954) of the Conway (1950) microdiffusion technique which shows the ammonia level in the peripheral venous blood of normal people to be 55.6 (44.0-71.0) μg . of ammonia nitrogen per 100 ml. There is evidence that abnormally high levels of ammonia nitrogen in the blood reflect changes in the actual free ammonia level in the blood (McDermott and Riddell 1954).

The sodium glutamate for intravenous use was prepared by the method of Mayer-Gross and Walker (1949) and given in doses of 25 g. A few patients were treated with intravenous sodium succinate in doses of 10 g.

Results

The results of studies made on 29 patients with hepatic coma or pre-coma are summarised in the accompanying table. Patients with hepatic coma have a high blood-ammonia level related to the severity of their symptoms. The pattern of the blood-ammonia levels varies, but two predominant types are illustrated by the following case-histories:

Case 1.—A chronic alcoholic woman, aged 47, vomited a pint of blood on the eve of admission to hospital. Next

SUMMARY OF STUDIES ON PATIENTS WITH HEPATIC COMA

Case no.	Age (yr.)	Sex	Diagnosis	Days under observation, and outcome	Neurological state	Blood-ammonia levels (μg . per 100 ml.)	Comments
1	47	F	Alcoholic cirrhosis; bleeding oesophageal varices	3 Died	Within 12 hr. of onset progressed to deep coma with convulsions	518-115	Treatment with intravenous sodium glutamate was followed by fall of blood-ammonia level, but patient did not improve
2	39	M	Alcoholic cirrhosis	8 Died	Admitted in gross confusion, progressed to coma and death	463-189-235	Died in hepatic coma after temporary fall in blood-ammonia level accompanied by transient clinical improvement
3	62	M	Alcoholic cirrhosis; bleeding oesophageal varices	1 Died	Drowsy and confused	451	Died of massive hemorrhage within 12 hr. of onset
4	52	M	Alcoholic cirrhosis; bleeding oesophageal varices	48 Recovery	Admitted in coma precipitated by hemorrhage	412-53	Treatment with intravenous sodium succinate was followed by recovery for four days, but patient died of postoperative sepsis
5	49	M	Alcoholic cirrhosis; pulmonary tuberculosis	9 Died	Increasing drowsiness progressing to coma and death	76-408	Died of hepatic coma with rising blood-ammonia level
6	71	M	Alcoholic cirrhosis	18 Died	Recurrent attacks of stupor; improved temporarily and later died in coma	146-396	Terminal episode despite restriction of protein
7	49	M	Alcoholic cirrhosis	32 Recovery	Recurrent attacks of drowsiness and confusion with development of flapping tremor	393-142	Attacks related to high-protein intake associated with rise in blood-ammonia level
8	42	M	Alcoholic cirrhosis; bleeding oesophageal varices	16 Recovery	Admitted in coma which had lasted 12 hr.	385-94	Blood-ammonia level fell off rapidly
9	24	F	Acute virus hepatitis	4 Died	Stuporous when first seen, progressive deterioration	232-383	Treated with intravenous sodium glutamate
10	54	F	Hemochromatosis	11 Died	Became progressively worse during study and died in coma	92-380	Progressive deterioration with rising blood-ammonia level despite sodium glutamate and succinate
11	55	M	Alcoholic cirrhosis	6 Died	In deep coma throughout study	272-374	Coma probably induced by high-protein diet
12	38	F	Alcoholic cirrhosis	3 Died	Admitted in deep coma and continued in this state until death	300-355	On one day treatment with sodium glutamate 25 g. was followed by fall of blood-ammonia level to 165 μg . per 100 ml. without clinical improvement
13	41	M	Alcoholic cirrhosis; bleeding oesophageal varices	95 (2 admissions) Died	Normal except for one episode of semicoma lasting 3 days	(1) 75-106 (2) 219-59-343-76-275-122	219 at onset semicoma, 343 no symptoms; probably related to high-protein diet; died from postoperative sepsis
14	62	F	Portal cirrhosis	15 Died	Progressive deterioration ending in coma and death	51-333	On high-protein diet
15	47	M	Alcoholic cirrhosis; bleeding oesophageal varices	8 Died	Varied between semicoma and deep coma during study	147-312	Progressive deterioration with rising blood-ammonia level

morning, Oct. 25, 1953, her husband noticed that she was drowsy and arranged for her admission. During the next six hours she became increasingly worse until she was maniacal and finally lapsed into deep coma.

On admission in the maniacal stage her blood-ammonia level was 518 μg . of ammonia nitrogen per 100 ml. She was treated with intravenous dextrose, aureomycin, and sodium glutamate but in spite of this therapy remained in deep coma until death (fig. 1), although her blood-ammonia level fell to a relatively low figure—115 μg . of ammonia nitrogen per 100 ml.

Comment.—There are several interesting features in this case. If the patient's blood-ammonia level had not been determined before the second day, no relationship between her neurological condition and blood-ammonia level would have been apparent. This pattern of blood-ammonia levels has been observed also in cases 4, 7, 8, 21, and 24, who all recovered from their coma, but none had such a high initial blood-ammonia level.

Case 1 appears to have had a syndrome comparable to that seen in dogs and humans with Eck fistulæ, where it has been shown that a rise of blood-ammonia level induces symptoms which persist after the blood-ammonia level has fallen to nearly normal (McDermott and Adams 1954, Riddell et al. 1954).

Case 5.—A chronic alcoholic man, aged 49, was admitted to hospital on Sept. 23, 1953, with two months' history of abdominal swelling. A year earlier he had been treated in another hospital for portál cirrhosis with ascites.

On examination he was wasted and jaundiced; his abdomen was grossly distended with fluid, his liver was enlarged, and he had severe bilateral pulmonary tuberculosis, with tubercle bacilli in his sputum. Liver-function tests on Sept. 24 showed total serum-protein 5.3 g. per 100 ml. (albumin 1.1 g. per 100 ml.); and total serum-bilirubin 3.3 mg. per 100 ml. There was no neurological abnormality on admission, but on Oct. 2 the patient became drowsy. His condition became progressively worse, and on Oct. 7 he went into deep coma and remained in this state until he died on Oct. 10 (fig. 2).

Comment.—The pattern of a progressive rise in blood-ammonia level (fig. 2) is that seen in patients with terminal hepatic failure (see table). The blood-ammonia level rose from an initial reading of 76 μg . of ammonia nitrogen per 100 ml. on Oct. 2 to 408 μg . per 100 ml. on Oct. 7, then fell on Oct. 8, but rose again next day, and on the day of his death (Oct. 10) was 313 μg . per 100 ml. The administration of relatively large amounts of protein may have contributed to his death. The rise in the blood-ammonia level followed an oral intake of

SUMMARY OF STUDIES ON PATIENTS WITH HEPATIC COMA—continued

Case no.	Age (yr.)	Sex	Diagnosis	Days under observation, and outcome	Neurological state	Blood-ammonia levels (μg . per 100 ml.)	Comments
16	26	M	Cirrhosis with ulcerative colitis	9 Died	Drowsy on admission, died in coma	103-311	Temporary improvement on intravenous sodium glutamate, with fall in blood-ammonia level
17	66	M	Alcoholic cirrhosis	9 Died	Drowsy, confused about place and time	131-300	Precipitated by ammonium chloride; temporary lowering of blood-ammonia level to 73 μg . per 100 ml. after treatment with intravenous sodium glutamate, with improvement; died of coronary thrombosis
18	44	M	Cirrhosis; hæmochromatosis; bleeding oesophageal varices	40 Recovery	Became comatose after hæmorrhage; recovered rapidly	88-291-146	Highest blood-ammonia level preceding coma 203 μg . per 100 ml.; died of recurrent hæmorrhage from varices
19	43	F	Alcoholic cirrhosis	22 Recovery	Drowsy and confused with flapping tremor	290-134	Recovery with fall in blood-ammonia level after therapy with intravenous sodium glutamate
20	43	M	Alcoholic cirrhosis; bleeding oesophageal varices	5 Died	Increasing drowsiness progressing to semicoma	138-285	Died from hæmorrhage on fifth day
21	65	F	Alcoholic cirrhosis	3 Died	In semicoma, responding to painful stimuli only	253-131	Coma precipitated by course of ammonium chloride; given intravenous sodium glutamate on admission; this was followed by improvement with fall in blood-ammonia level; patient died suddenly of brain-stem hæmorrhage; no necropsy
22	52	F	Postnecrotic scarring; bleeding oesophageal varices	11 Recovery	First seen in deep coma; recovery	252-82	Treated with intravenous sodium glutamate and succinate; recovered from coma; died later from post-operative pulmonary oedema
23	67	M	Portal cirrhosis; bleeding oesophageal varices; polycythæmia vera	2 Died	Two days before study patient started to bleed, rapidly passed into coma, and died	250-167	Not seen until in coma; given intravenous sodium glutamate on day of death
24	53	M	Alcoholic cirrhosis	31 Died	Drowsy during part of study	95-245-96	Died of pneumonia; peak blood-ammonia level coincided with onset of neurological symptoms
25	57	M	Portal cirrhosis; bleeding oesophageal varices	20 Recovery	For one day very drowsy after transoesophageal ligation of varices	214-25	..
26	55	M	Alcoholic cirrhosis	7 Recovery	Confused and disoriented	195-100	Improvement coincided with fall in blood-ammonia level
27	43	M	Alcoholic cirrhosis; bleeding oesophageal varices	2 Died	Admitted in deep coma, improved on therapy	169-108	Improvement followed treatment with intravenous sodium glutamate; blood-ammonia level not estimated before therapy started; patient died of uncorrected hypokalæmic alkalosis
28	34	M	Alcoholic cirrhosis; bleeding oesophageal varices	2 Died	In deep coma when first seen; died next day	158-132	Blood-ammonia level not determined until after patient had been in coma 24 hr.
29	40	M	Alcoholic cirrhosis	2 Died	In semicoma for a week before study; died in coma	103-129	Patient seen only 48 hr. before death. blood-ammonia level not estimated at onset of coma.

120 g. of protein on Oct. 5; and the highest blood-ammonia level of 408 µg. per 100 ml. corresponded to an intake of 85 g. of protein on Oct. 7.

Case 9.—A woman, aged 24, received a blood-transfusion for post-partum hæmorrhage four months before admission on Dec. 11, 1953. She was well until nine days before admission, when she first became ill with malaise, nausea, and vomiting; two days later she became jaundiced.

On admission she was deeply jaundiced, drowsy, and disoriented. Apart from these findings physical examination was negative. Over the next two days her condition became worse; she was very drowsy and slept unless stimulated, when, if roused, she was disoriented and excitable. Treatment was started with cortisone 400 mg. daily.

Subsequent Progress.—On Dec. 14 she was stuporous but, if stimulated, she had bouts of screaming. Her blood-ammonia level was 232 µg. of ammonia nitrogen per 100 ml. On Dec. 15 she was comatose, showing only a feeble response to painful stimuli. Her blood-ammonia level was 254 µg. of ammonia nitrogen per 100 ml. in the morning. In the afternoon her physical condition was unchanged, but her blood-ammonia level had fallen to 156 µg. of ammonia nitrogen per 100 ml., and it fell still further to 74 µg. per 100 ml. after the administration of intravenous sodium glutamate 25 g. In response to the glutamic-acid therapy there was a slight clinical improvement in that, although remaining in coma, the patient reacted by feeble movements to light touch. On Dec. 16 she was in deep coma until she died soon after midnight; two hours before death muscle twitching developed. The blood-ammonia level rose from 234 µg. of ammonia nitrogen per 100 ml. in the morning to 383 µg. per 100 ml. in the afternoon. Necropsy showed acute yellow atrophy of the liver.

Comment.—This patient showed the progression of hepatic coma from stupor to deep coma, and over this period her blood-ammonia level rose from 232 to 383 µg. of ammonia nitrogen per 100 ml. Glutamic-acid therapy was associated with a transient fall in the blood-ammonia level but did not produce any definite clinical improvement.

Fig. 2—Case 5: correlation between blood-ammonia level and neurological state in terminal hepatic failure. Electro-encephalography was not done.

disturbed consciousness do not show the abnormal rhythm attributed to hepatic coma. In these patients the blood-ammonia level was not much raised, and they have been excluded from the series because the cause of their neurological disturbance was considered to be due to other complications of hepatic disease—e.g., electrolyte disorders, septicæmia, severe pulmonary infection, and neurological disorders associated with chronic alcoholism.

Of the 29 patients 11 were treated with glutamic acid, with the following results:

Number of patients treated	11
Number of patients who improved on therapy	6
Number of patients who recovered from hepatic coma	3
Number of patients who left hospital	1*

* 2 patients died of intercurrent disease.

To 3 patients in deep coma only one infusion of sodium glutamate 25 g. was given; all of these died without showing any improvement. Of 8 patients treated with intravenous glutamic acid in repeated doses earlier in the disease 6 improved temporarily, and 3 recovered.

We tried to obtain objective evidence of the value of glutamic-acid therapy by observing its effect on peripheral blood-ammonia levels. In all 7 cases in which this was studied the blood-ammonia level fell after the administration of glutamic acid, and in 4 patients this was followed by clinical improvement. The results of one such experiment are given in fig. 3, which shows that the blood-ammonia level fell after the administration of intravenous sodium glutamate on two occasions (between the two infusions intravenous therapy was continued with glucose). Although a temporary clinical improvement took place in this patient, his condition deteriorated and he died in hepatic coma. In this case the sodium glutamate became decreasingly effective in lowering the blood-ammonia level as the patient's condition became worse.

Discussion

In any discussion of hepatic coma it is important, first of all, to stress the concept that there is not a single disorder attendant on acute or chronic deterioration in hepatic function. The susceptibility of patients with liver disease to infection, the electrolyte disturbances associated with advanced cirrhosis, and the development of hypoglycæmic attacks in patients with cirrhosis are only a few of the disorders which may cause a variety of symptoms, including neurological disturbances. In addition, chronic alcoholism, one of the major causes of cirrhosis, has associated neurological diseases—e.g., the Wernicke-Korsakoff syndrome and delirium tremens. We are concerned here only with a specific biochemical abnormality which our observations indicate to be a cause of consistent neurological symptoms and electro-encephalographic changes, both of which may be completely reversible. In our experience most cases of so-called hepatic coma are due to this specific abnormality—ammonia intoxication.

The results reported here show a correlation between the neurological symptoms and the ammonia levels in the peripheral blood in hepatic coma in 28 patients with cirrhosis of the liver and 1 with virus hepatitis. This observation alone does not establish that ammonia intoxication causes neurological conditions, but other experimental and clinical evidence supports this concept.

Ammonia is known to be very toxic to animals; to rabbits it is lethal at a concentration of about 1 part in 20,000 (Baldwin 1952). The Eck-fistula dog, when given ammonium salts, urea, or meat, develops a neurological syndrome characterised by ataxy, amaurosis, coma, and sometimes death, which is called "meat intoxication." The episodes of intoxication are preceded by high ammonia levels in the peripheral blood, and the symptoms may persist although the blood-ammonia level has fallen to nearly normal. This syndrome can be induced by repeated small injections of intravenous urease, when

Fig. 3—Case 16: effect of intravenous sodium glutamate on blood-ammonia level. In each instance the intravenous infusion of sodium glutamate was followed by a fall in blood-ammonia level, which rose again when the infusion was discontinued.

In this investigation electro-encephalography showed changes closely correlated with the clinical and biochemical findings, and revealed that some patients with

both the symptoms of meat intoxication and the same pattern of blood-ammonia levels are observed (Riddell et al. 1954).

In cirrhosis of the liver symptoms identical with those of the onset of hepatic coma have been produced by the oral administration of ammonium salts and compounds which might liberate ammonia, such as urea (Phillips et al. 1952). Treatment of hepatic coma by a method which aims at enhancing the activity of one of the mechanisms of detoxication for ammonia—i.e., glutamic-acid therapy—is effective in some cases (Walshe 1953). Our results show that glutamic-acid therapy may cause clinical improvement and its use is followed by a fall in blood-ammonia level.

It is believed that the observed changes in peripheral blood-ammonia levels in hepatic coma do not give more than a general indication of the changes in ammonia metabolism which take place in the brain-cells, where ammonia is constantly being formed and then removed by the glutamic-acid/glutamine system (Weil-Malherbe 1950).

While in "meat intoxication" in the Eck-fistula dog and the episodic stupor which sometimes follows porta-caval anastomosis in man the part played by ammonia intoxication appears clear, this is not always so in patients dying of liver failure. In such patients there are commonly present other disorders which may cause changes in consciousness—e.g., electrolyte disorders, hyponatraemia, hypokalaemia, septicaemia, and severe respiratory infections. Any of these may occur in association with ammonia intoxication.

Our experimental findings do not warrant a discussion of the treatment of hepatic coma, but certain observations may be made. First, we must emphasise again the observations of Davidson and his co-workers (Gabuzda et al. 1952, Phillips et al. 1952) on the potential dangers of a high-protein diet and of ammonium-containing compounds in decompensated liver disease; but the therapeutic value of protein in compensated liver disease must also be emphasised. Glutamic-acid therapy in hepatic coma has not yet been proved to be of value. In patients with terminal hepatic failure little can be expected except some temporary improvement, but in patients in whom the symptoms are due to relatively mild ammonia intoxication the chances of recovery may be enhanced by treatment with glutamic acid, whose greatest usefulness may be in patients showing evidence of impending coma after haemorrhage from oesophageal varices.

Summary and Conclusions

In hepatic coma the metabolism of ammonia is deranged.

The evidence for the existence of ammonia intoxication in hepatic coma is discussed, and it is believed that it is sufficient to base therapy on this concept of ammonia intoxication.

The place of glutamic-acid therapy in hepatic coma is discussed.

THE TREATMENT OF ERYTHROBLASTOSIS FŒTALIS WITH Rh HAPTEN

REVIEW OF A HUNDRED CASES

BETTINA B. CARTER

Ph.D.

ASSISTANT PROFESSOR OF BACTERIOLOGY IN THE COLLEGE OF MEDICINE, NEW YORK STATE UNIVERSITY IN SYRACUSE, SYRACUSE, N.Y.

From the Institute of Pathology, Western Pennsylvania Hospital, Pittsburgh, Pennsylvania

THE suggestion that erythroblastosis foetalis, foetal oedema, icterus gravis neonatorum, and anaemia of the newborn were manifestations of a single disease was first put forward by Diamond, Blackfan, and Baty (1932). Darrow (1938) suggested that this disease was caused by destruction of foetal red cells by some immunity reaction. Levine and Stetson (1939) reported an agglutinin in the blood of a mother delivered of a dead foetus; this antibody had properties similar to those of agglutinins which had been produced in rabbits by the injection of red cells of *Macacus rhesus* (Landsteiner and Wiener 1940).

From this beginning has expanded our modern concept of erythroblastosis foetalis as a disease produced by maternal immunisation to a foetal-blood factor inherited from the father. This Rh factor has been obtained from the stroma of human red cells by Belkin and Wiener (1944) and Calvin et al. (1946). Carter (1947) reported a crude red-cell fraction which inhibits anti-D (anti-Rh₀) serum and described this in detail (1949) under the name of Rh hapten. This substance is produced from Rh-positive (pooled CDE positive) human red cells by protein precipitation with alcohol and further extraction of lipid constituents, originally with ether, at present with the non-inflammable compound dichloromethane, as suggested by Smolens (1952). 100 mg. of the substance so extracted, when mixed with 1 ml. of a potent anti-D serum and the mixture incubated at 37°C for 30 minutes, will absorb a high percentage of Rh antibodies from that serum, as determined by serum titrations and by quantitative nitrogen determinations of the washed serum-exposed fraction particles.

Present Investigation

The fraction has been injected intramuscularly into more than 500 sensitised Rh-negative pregnant women, and I report here the results obtained in the first 100 cases treated at the Western Pennsylvania Hospital in Pittsburgh. Although the clinical material is heterogeneous, consisting of cases presenting in sequence, and although many of these women received treatment which was inadequate by present standards—which have been achieved only by trial and error—the results were promising (table 1). All the serological procedures

N.B.—Those babies transfused were delivered at hospitals other than the Western Pennsylvania Hospital.

were done in the laboratory for research immunology at the Western Pennsylvania Hospital, and the presence of maternal Rh antibody was confirmed in each case by Dr. Bruce Chown of Winnipeg.

Inasmuch as it is common experience among investigators in the field to observe cases of normal Rh-positive children born to sensitised Rh-negative mothers who had not previously had babies with erythroblastosis, I am not emphasising the results in subsample 1. However, it seems unlikely that results such as these would occur in 29 consecutive cases without treatment. Subsample 2 has been studied in detail, and a complete chronicle can be obtained from me. The cases included in this study are those in the Pittsburgh area—treated sensitised women delivered in hospitals near enough for observation of the progress of the infants. These women came to the Western Pennsylvania Hospital for treatment. Of the 56 cases in subsample 2, 46 were referred by outside physicians because of previous difficulties due to Rh sensitisation. Since a few women came in for one or two injections and then abandoned the project, only those are included who received at least 800 mg. of red-cell fraction during a pregnancy. However, every case in the Pittsburgh area in which 800 mg. or more was injected is considered consecutively. Each live-born baby in the treated series was observed by me. Extensive study was made of hospital records to obtain all the facts available concerning each pregnancy in each case before the one in which the mother was treated.

The red-cell fraction is used primarily for the treatment of the Rh-negative sensitised women rather than for the infants after they are born. Each prospective mother is under the care of her own physician and has been referred by him for injections of the red-cell fraction at his request. The current regimen requires a patient who has lost one or more infants because of erythroblastosis to begin treatment not later than the third month of pregnancy, and preferably just after the first missed period. In some cases treatment is begun before pregnancy is established. The already pregnant patient is admitted to hospital and given 400 mg. of red-cell fraction four-hourly day and night until 18 injections have been given. She is then discharged with a supply of red-cell fraction, 200 mg. per ampoule, and her husband is instructed to inject the contents of one ampoule daily. This is continued until term, with the patient reporting every week or every two weeks for antibody titrations and a new supply of ampoules.

The contents of one ampoule (200 mg. in alcoholic solution) are suspended in 6 ml. of sterile physiological saline solution, and the whole is injected *slowly* into the gluteal muscles from a 10-ml. syringe and a 20-gauge 2-inch needle. No reactions have been observed except occasional local soreness. The regimen outlined above leads to the administration of a greater volume of the red-cell fraction than was given to most of the women in table I. There is a tendency with experience to use larger dosages of the red-cell fraction and to attempt to keep the patient saturated.

Discussion

The mode of action of red-cell fraction in the body is not clear. The obvious explanation is that the material is a hapten, and that it neutralises maternal antibodies to Rh. However, the substance seems to exert a directly protective effect on red cells of the infant. In this laboratory maternal antibody titres have shown a consistent falling off under treatment with the red-cell fraction. Goldsmith (1950) has reported similar observations. Some workers have not observed this, but perhaps the smaller volume of total injections explains why they have not done so. The importance of beginning injections of the red-cell fraction very early may be explained by the postulate that, if this substance is hapten, it is

TABLE II—RELATION OF OUTCOME TO MATERNAL HISTORY AND REFERRAL

Totals	29	10	46

of value to use it at least as soon as there are formed elements in the foetal circulation. According to Patten (1946) the foetal heart-beat is established by the end of the third week after fertilisation.

It is difficult to elucidate the real significance of any method of treatment of erythroblastosis, because studies in the natural history of the disease are almost non-existent. Several papers have been published which have given results of pregnancies in Rh-negative sensitised women, but none of these constitute presentations of natural history, because in every case attempts were made to alleviate the disease. Allott and Holman (1949) reported a study of 117 infants with a total mortality of 56%—a mortality of 48% for infants from mothers sensitised only in the current pregnancy, and a mortality of 71% for infants from mothers who have had previous erythroblastotic babies. A comparable breakdown for the present series gives a total mortality of 33%—a mortality of 7% for babies whose mothers became sensitised to Rh with the current pregnancy, and a mortality of 47% for infants whose mothers had erythroblastotic babies previously.

Chown (1952) suggests that the results of treatment should be categorised by assessing whether a current treated pregnancy showed an improved outcome over a previous one or provided a less promising result. Such an analysis of the 56 cases in subsample 2 (table I), after the omission of 14 which, although presumptive, did not provide histories adequate to prove erythroblastosis unequivocally, gives the following picture: improved outcome, 18 cases; poorer outcome, 8 cases; change in results negligible, 16 cases.

The studies of Vaughan et al. (1950), at Harvard Medical School, have provided information as to the relation of outcome to maternal history. A comparison of their series with the present one is of value only if variables are taken into account. The period of their reported investigation includes many cases in which labour was induced before term, a practice which Vaughan et al. feel may conduce to the incidence of kernicterus. With rare exceptions the infants reported in our series were allowed to go to term. In the Harvard series, with exchange transfusion the method of treatment, there were 26% stillborn to 21% in our series, and 54% surviving babies to 67% in our series. The outstanding difference in the two series may be found in those infants with no clinical disease: 18% in the Harvard series and 42% in ours. This difference in the number of normal infants is the only one which can be concluded to have high statistical significance (t of 3.9 at the 0.01 level).

Table II is modelled on table IV of Vaughan et al. (1950). "Referred" means any woman who had her previous erythroblastotic baby in another hospital; "not referred" means one who had her previous erythroblastotic baby in the Western Pennsylvania Hospital.

The category "no clinical disease" in table II is not identical with "normal babies" in table I. "No clinical disease" means entirely free from clinical evidence of

erythroblastosis, whereas "normal babies" include all babies not transfused yet developing normally, of whom a few had very mild clinical disease, such as would be overlooked in the average practice.

Summary

The results of injecting red-cell fraction into Rh-negative sensitised women during their pregnancies are presented in detail as regards the 85 Rh-positive infants.

The method of administration and the possible action in the body of the red-cell fraction are discussed.

The results are analysed, and the conclusion is drawn that treatment of the mother with the red-cell fraction increases the number of normal babies.

I am indebted to Dr. Bruce Chown, of the Children's Hospital, Winnipeg, Canada, for his kindness in checking parent and infant phenotypes and maternal antibody titres and for suggestions and interest. I am grateful also to Mr. Daniel F. Jackson, now with the New York State University College of Forestry, for his statistical analyses of the data. Mr. Vincent Yakulis did much of the laboratory work and Mr. Daniel F. Jackson, Mrs. Elizabeth Lewis, and Mrs. Betty deWeeger assisted with "record-room" research.

URINARY EXCRETION OF POLYVIDONE

A. W. WILKINSON

M.B., Ch.M. Edin., F.R.C.S.E.

LECTURER IN SURGERY IN THE UNIVERSITY OF EDINBURGH

I. D. E. STOREY

B.Sc., Ph.D. Edin.

MEMBER OF EXTERNAL STAFF, MEDICAL RESEARCH COUNCIL

A SOLUTION of polyvidone (polyvinylpyrrolidone) was first used as a substitute for plasma by Hecht and Weese (1943). We used a 3.5% solution whose detailed composition has been described by Thrower and Campbell (1951); its viscosity, colloidal osmotic pressure, and tonicity are about the same as those of normal human blood.

In a clinical trial of this solution one of us (A. W. W.) infused 500-4000 ml. into each of 75 patients whose blood volume was judged on clinical grounds to be reduced (table 1). 23 of the patients died of the effects of their disease or injuries. At necropsy of 20 of these no macroscopical or microscopical evidence was obtained of accumulation of polyvidone in liver, spleen, kidneys, lung, or lymph-glands, but in the absence of a specific stain for polyvidone this evidence is inconclusive. No evidence of toxicity was obtained.

Polyvidone is not metabolised in the body (Ravin et al. 1952), and it is important to know what happens to it after it has been infused. In these patients the direct measurement of changes in plasma volume was impracticable, and measurements of the plasma-polyvidone levels were unsatisfactory; hence the rate of loss of polyvidone from the circulation could not be ascertained. It was possible, however, to measure the quantity of polyvidone excreted in the urine, and from these observa-

tions some conclusions have been drawn about the possible distribution of polyvidone in the body.

Methods

After operation in 20 cases the urinary content of polyvidone was measured by the method of Thrower and Campbell (1951) with a Spekker absorptiometer with Ilford blue-green spectrum filter; readings were taken a minute after the addition of the iodine reagent. The analyses were usually continued until only traces of polyvidone could be found. The duration of the collections varied from 45 to 260 hours after the start of the polyvidone infusion and exceeded 72 hours in 13 cases and 100 hours in 11 cases. These 20 cases have been considered first according to the total quantity of polyvidone excreted, and secondly according to the rate of excretion (table II).

TOTAL QUANTITY OF POLYVIDONE EXCRETED

Polyvidone equivalent to more than 70% of the quantity injected was recovered in the urine of 5 patients; in 9 others the equivalent of 50-70%, and in 5 patients of 40-50%, of the dose was recovered; in 1 case less than 30% was recovered after each of two infusions. The largest quantity recovered was 78% of the dose within 72 hours after an emergency gastrectomy (Polya) for a perforated duodenal ulcer in a patient to whom 500 ml. of 'Plasmosan' (17.5 g. of polyvidone) had been administered. There did not appear to be any relationship between the quantity of polyvidone administered and quantity excreted in the urine; the smallest recovery (27%) followed the largest dose (1500 ml. of plasmosan containing 52.5 g. of polyvidone). Another patient (case 12), who received two separate infusions, excreted 51% of the total dose; after the first infusion only 33% of the dose was excreted, but after the second infusion the equivalent of 86% of the second dose was excreted; this suggests that some polyvidone from the first infusion was retained until after the second infusion had been administered.

RATE OF EXCRETION

When the urinary excretions of polyvidone were plotted against time, it was evident that the patients fell into four groups, typical examples of which are shown in the accompanying figure:

(1) In the first group (exemplified by case 6 in the figure) there were 5 patients who each excreted more than 50% of the dose (and 3 more than 60%) within 24 hours of the infusion; the rate of excretion then fell off, but 2 had excreted more than 70% in 72 hours, and 1 other more than 70% in 90 hours.

(2) The main group of 13 patients, most of whom excreted 30-50% in 24 hours, can be divided into two parts: (a) 3 patients in whom excretion began as rapidly as in the first group, 2 excreting more than 30% of the dose within 12 hours (exemplified by case 14 in the figure), but the rate of excretion fell off between 12 and 24 hours; and (b) the remaining 10 patients, whose excretion began slowly and then increased rapidly with the result that, despite the initial delay, in 5 of these patients more than 40% was excreted within 36 hours (exemplified by case 4 in the figure).

Patterns of urinary excretion of polyvidone in four patients representing four different types of excretion.

(3) The last group, of 2 patients who excreted less than 10% in 24 hours and only 30% in 80 hours (exemplified by case 19 in the figure).

The most rapid early excretion was of 7 g. of polyvidone, equivalent to 21% of the dose within 6 hours, but this patient excreted only 39% in 24 hours and 50% in 102 hours. Small quantities of polyvidone were recovered from the urine within 3 hours of the start of an infusion of plasmosan. When excretion was at its height, the urinary concentration of polyvidone was usually 1-2%, but higher concentrations up to 5% were also found.

There seems to be some relationship between the total quantity of polyvidone excreted in the first 24 hours and the rate of formation of urine. Of the 7 patients who excreted more than 60% of the dose of polyvidone 5 excreted more than 55% of the dose in the first 24 hours and during this period excreted more than 800 ml. of urine. Of the remaining 2 patients 1 excreted 27% of the dose in the smallest 24-hour volume of urine (405 ml.) and the other excreted 47% of the dose in the largest volume of urine (1375 ml.) of this group. In the remaining 13 patients the lower outputs of polyvidone during the first 24 hours were usually associated with smaller 24-hour volumes of urine. When the output of polyvidone had been small during the first 24 hours, diuresis in the second 24-hour period was often accompanied by the excretion of a large quantity of polyvidone.

Discussion

The rate of urinary excretion of polydisperse macromolecules, such as polyvidone and dextran, has been shown in uninjured animals to be inversely proportional to their molecular weight (Grotte et al. 1951, Steele et al. 1952). When the excretion of polyvidone was plotted against time, it was found in 18 out of our 20 cases that the shape of the curve was similar to that which Thrower and Campbell (1951) had suggested was typical for polyvidone. These curves closely resemble that for the excretion of inulin which Schwartz et al. (1949) stated was characteristic of the excretion of a non-metabolisable substance of large molecular weight. Ravin et al. (1952), who injected polyvidone labelled with I¹³¹ or C¹⁴ into dogs, rats, rabbits, and man, concluded that polyvidone was not metabolised, and that excretion by routes other than the urine was insignificant. Although the shape of the curves was typical, there was considerable variation in the total quantity of polyvidone excreted and in the time at which rapid excretion began. There was a delay in the onset of excretion of polyvidone of 12 to 24 hours or more in 9 of 20 people, the most likely cause of which seemed to be postoperative oliguria. Ravin et al. (1952) found that the total quantity of polyvidone excreted was independent of the rate of formation of urine when this exceeded 800-1000 ml. per 24 hours; this rate was achieved during the first 24-48 hours in only 8 of our 20 patients.

Detailed characterisation of the distribution of molecular weights in the polyvidone preparation used in these experiments was not available to us. It seems likely, however, that, if the equivalent of more than 60% of the polyvidone in a standard preparation was excreted within 24 hours of infusion by 3 people, this preparation contained a high proportion of material of low molecular weight. This conclusion is supported by the recovery of 70-80% in 4 cases. Ravin et al. (1952) concluded that, for polyvidone, molecules having a molecular weight of 40,000 were the largest that could be excreted in the urine. Since polyvidone is not metabolised in the body, this would imply that nearly 80% of the polyvidone in this preparation had a molecular weight of less than 40,000. Although osmotic effect is inversely proportional to size, increase in plasma volume depends on the retention of the active agent within the blood-vessels. Other capillaries as well as those of the renal glomeruli are permeable to polyvidone of a molecular weight of less than 40,000; hence within a short time after the infusion

TABLE II—URINARY EXCRETION OF POLYVIDONE

Case no.	Age (yr.)	Sex	Diagnosis and treatment	Volume of plasmosan injected (ml.)	Dose of polyvidone (g.)	Percentage of total dose of polyvidone excreted in urine			Duration of estimation of urinary polyvidone (hr.)
						In 24 hr.	In 48 hr.	Total	
1	37	M	Perforated duodenal ulcer; emergency partial gastrectomy	500	17.5	64.7	73.2	78.0	72

a large proportion of these smaller molecules will be distributed in the interstitial fluid rather than in the plasma. As the level of small polyvidone molecules in the plasma is lowered by their excretion in the urine, other small polyvidone molecules probably pass back from the interstitial fluid into the plasma and are then in their turn available for excretion. Possibly variation in this type of equilibration may explain some of the differences observed in the urinary excretion of polyvidone. A preparation with such a high potential wastage in the urine is unlikely to produce consistently large and lasting increases in plasma volume.

Summary

The urinary excretion of polyvidone after the infusion of a 3.5% solution of polyvidone (plasmosan) was measured in 20 patients.

The total urinary excretion of polyvidone was equivalent to more than 70% of the dose in 5 patients, 50-70% in 9, 40-50% in 5, and less than 30% in 1 patient.

Within 24 hours of the infusion the equivalent of more than 55% of the dose was excreted by 5 patients, 30-50% by 13, and less than 10% by 2 patients.

Possible explanations of these variations are discussed.

Messrs. May & Baker Ltd. supplied the plasmosan.

HYPERTENSION AND "VENOUS" LEG ULCERS

S. T. ANNING

M.A., M.D. Camb., M.R.C.P.

ASSISTANT PHYSICIAN, DERMATOLOGICAL DEPARTMENT, GENERAL INFIRMARY, LEEDS

In a series of patients with either post-thrombotic or varicose ulceration of the leg the arterial blood-pressure was determined (Anning 1949, 1952). The men formed a group too small for conclusions to be drawn from their blood-pressure readings, but after division into age-groups the blood-pressure records of the women were compared with the figures presented by Robinson and Brucer (1939) based on 3405 American women taken at random. The proportion of ulcer patients with hypertension was found to be significantly higher than in Robinson and Brucer's controls. The criteria of hypertension used by these workers have been criticised by Hamilton et al. (1954), who publish tables showing the mean casual arterial blood-pressure of a sample of the general population, thus making it possible to determine whether the average arterial blood-pressure of leg-ulcer patients is within the normal range or not. The results of such a comparison are presented here.

Investigation

In this investigation the casual arterial blood-pressure of 696 women and 316 men with either post-thrombotic or varicose leg ulcers was determined with a mercury Riva-Rocci sphygmomanometer. The precautions and methods of Hamilton et al. (1954) were used, though only about 85% of the observations were made by me, the remainder being made by several house-physicians. In about 0.5% the blood-pressure was determined when the patient was in bed in hospital. All the patients were weighed. The series includes the patients considered in previous papers (Anning 1949, 1952) together with others examined since.

Tables I and II show the results obtained compared with those of Hamilton et al. (1954). It will be noted that there is a significant difference—i.e., more than twice the standard error of the difference between the means—between the systolic and diastolic pressures of women aged 35-74 and the diastolic pressures of men aged 40-54. There is also a significant difference between the systolic pressures of men aged 40-44 and men aged 50-54. In these various groups it is shown that the ulcer patients have a higher arterial blood-pressure than the sample of the general population. Groups containing fewer than 20 patients have not been compared.

Discussion

The sample of the population investigated by Hamilton et al. (1954) included 421 women and 276 men with varicose veins out of a total of 1204 women and 827 men. These workers found that women with varicose veins showed a significantly more rapid rise of systolic pressure with age. This is of importance in relation to the ulcer patients, many of whom had varicose veins. In addition it would "weight" the control group, tending to lessen the difference between the groups.

In the higher age-groups the difference between the groups tends to become less or to be reversed. This is, no doubt, partly because of the small numbers compared; but there is a probability that hypertensive patients will die before reaching a great age, and this will tend to reduce or obviate the difference between the groups as the age-groups become older.

The cause of the relationship between hypertension and ulceration from defective venous circulation is obscure and has been discussed elsewhere (Anning 1952). Hypertension with varicose veins or the predisposition to venous thrombosis might possibly develop in the same families, but this seems unlikely. In the present series there is no evidence that body-weight is a factor. The opening up of arteriovenous shunts after deep venous

thrombosis (Brewer 1950, 1951) and their importance in the aetiology of varicose veins (Piulachs and Vidal-Barraquer 1953) may prove to be of significance in relation to hypertension in these patients. The question whether such shunts lead to a rise in arterial pressure cannot be answered at present. In osteitis deformans arterial degeneration, sometimes with hypertension, is found in most patients aged more than 50 (Hunter 1946). This is a condition in which arteriovenous shunts tend to occur in affected bones, but there is no evidence that they are related to the rise in arterial pressure. Perhaps hypertension is a coincidental finding which, in patients with a defective venous return from the lower limbs, predisposes to ulceration.

(a) Present series. (b) Controls of Hamilton et al. (1954).
* A significant difference of means.

Summary

The casual arterial blood-pressure of 696 women and 316 men with either post-thrombotic or varicose ulceration of the limbs was compared with that of a sample of the general population determined by Hamilton et al. (1954).

The systolic and diastolic pressures of women, aged 35-74, with ulcers are significantly higher than those of controls. Of the men with ulcers those in some age-groups also had higher pressures.

The possible causes for these findings are discussed.

I am grateful to Dr. John T. Ingram, Dr. F. F. Hellier, and other colleagues and practitioners who have referred patients to me, and to Prof. G. W. Pickering for allowing me to see the paper by himself and his collaborators before publication.

IDIOPATHIC HYPERCALCAEMIA OF INFANTS
 LOW-CALCIUM TREATMENT

A. W. FERGUSON

B.A., M.B. Camb., M.R.C.P., D.C.H.

PÆDIATRIC REGISTRAR, CHILDREN'S HOSPITAL, BRISTOL

G. K. MCGOWAN

B.A., B.M. Oxfd

CONSULTANT CHEMICAL PATHOLOGIST, UNITED BRISTOL HOSPITALS

In idiopathic hypercalcaemia of infants (Lightwood 1952, Payne 1952) many of the symptoms (e.g., anorexia, constipation, and loss of muscle tone) may be the result of the hypercalcaemia itself. The cause of the hypercalcaemia is not yet established, but possible factors are impairment of renal excretion of calcium and excessive absorption of calcium from the gut. The latter might well occur in infants fed on cow's milk (which contains four times as much calcium as does human milk), patent cereals (many of which are fortified with calcium), and vitamin-D supplements. Whatever the cause, it seemed to us likely that a low-calcium diet would relieve the condition, and we therefore decided to try such a treatment.

Methods

It is not simple to make up an artificial low-calcium milk, because nearly all commercial casein contains calcium caseinate. Our first method, therefore, was to pass milk through a column of cation-exchange resin in such a way that most of the calcium was removed in exchange for potassium, sodium, and magnesium in about normal proportions. Black and Milne (1952) used the same principle to prepare a low-potassium diet. Our second method was to make up an artificial milk with a special low-calcium casein.

The apparatus used for the first method is shown in fig. 1. The main glass tube is about 24 in. long with an internal diameter of 1 in. It contains at least 100 g. of 'Amberlite' resin no. 1R 120 H, making a column about 10 in. high. The outflow tube is flexible and usually raised so that the level of fluid cannot fall below the top of the column; this prevents air from getting into the column and lowering its efficiency. When desired, the tube can be lowered and the fluid in the resin column drained off.

The column of resin rests on a perforated porcelain filter disc covered with a thin layer of cotton-wool to prevent small

Fig. 1—The apparatus.

particles of resin from getting through the perforations. This base is set in position with the tube already partly full of water so that no air will be trapped in or under it. The resin is next washed into the tube with plenty of water, the excess of which drains away through the outlet. When the resin has sedimented, the top of the column is covered with another thin layer of cotton-wool to prevent the upper layers from being disturbed by inflowing solutions, and the fluid level is adjusted to the top of the column. Fluid is run into the tube from a separating funnel, whose neck is stoppered with a bung bored to take an air-inlet tube, which reaches to the bottom of the chamber. The air which is drawn in bubbles up through the contents of the funnel and helps to prevent the cream from separating from the milk.

The resin is conditioned by running through it 500 ml. of a solution containing potassium, sodium, and magnesium at about forty times the concentrations found in cow's milk

Fig. 2.—Weight charts of 4 infants with hypercalcaemia, showing gain in weight on low-calcium milk. Interrupted lines denote weights before admission to hospital.

(0.8 M sodium chloride, 1.6 M potassium chloride, and 2.4 M magnesium sulphate) at a rate of about 150 drops a minute. The fluid level is adjusted to the top of the column. The column is next washed through with 500 ml. of a 1/40 dilution of the above-mentioned solution—i.e., equal to normal milk concentrations—at the same rate, and the fluid level is again adjusted to the top of the column. The resin is now charged with potassium, sodium, and magnesium in the correct proportions and is free from calcium.

When required, a pint of fresh milk can be run through the column at 150 drops a minute. The effluent is clear at first but gradually becomes milky. A volume equal to that initially present in the apparatus (about 80 ml.) is rejected, and all the subsequent effluent is collected. When the outflow has nearly ceased, the outlet tube is lowered, and the milk remaining in the apparatus is run off as completely as possible. The milk is immediately bottled as separate feeds and may be sterilised in the usual way.

After use the apparatus is emptied and the resin repeatedly washed in water, the resin being allowed to sediment, and the supernatant fluid being decanted until it is perfectly clear. The apparatus is thoroughly cleaned with soap and hot water and well rinsed. It is then reassembled and the column prepared as described.

Analysis of samples of milk treated in this way gave the following approximate cation concentrations compared with untreated cow's milk:

	Untreated	Treated
Calcium (m.eq. per litre)	60	1-5
Potassium	35	70
Sodium	20	40
Magnesium	10	15

Another form of low-calcium milk has been made up from Allen & Hanburys' "low-ash casein," which contains only traces of calcium. This protein is highly acid, and is first treated with alkali (about 60 ml. of N NaOH per 100 g.) to adjust the pH to the iso-electric point of casein (4.7). At this pH the protein is almost insoluble and is washed once with water and twice with acetone, allowing it to sediment, and drawing off the supernatant between washings. It is subsequently dried first in a stream of warm air and finally in a vacuum desiccator over P₂O₅. More recently we have found that even casein which contains large amounts of calcium can be rendered almost calcium-free by dissolving, precipitating at pH 4.7, washing, and drying.

This casein is used to make up an artificial milk approximating to human milk, except that the calcium content is low. To obtain 1 litre of milk, 20 g. of prepared casein is treated with 368 ml. of distilled water + 2.0 ml. of 4 N potassium hydroxide + 2.0 ml. of 2.5 N sodium hydroxide, mixed well, and stood for 1/2-1 hour at room-temperature with repeated gentle mixing to dissolve. Next the following solutions are added and mixed well: 2.0 ml. of 2.25 M dipotassium hydrogen phosphate, 2.0 ml. of 0.5 M potassium dihydrogen phosphate, 2.0 ml. of 0.5 M sodium sulphate, 2.0 ml. of 1.5 M magnesium chloride. This solution will keep for a few days in the refrigerator. On the day of use 500 ml. of water + 70 g. of lactose are added and the mixture is warmed to dissolve, autoclaved at 5 lb. for 10 minutes, and cooled. 60 ml. of this is added slowly, stirring with a sterile glass rod, to

60 ml. of pasteurised cream containing 50% fat. Next the diluted cream is added to the rest of the mixture, which is bottled as individual feeds in sterile containers and put in the refrigerator until wanted. The final composition of such a milk is as follows:

Fat	3%	(by calculation)
Lactose	7%	" "
Casein	2%	" "
Calcium	2 m.eq.	per litre (by analysis)
Potassium	18	" " " "
Sodium	9	" " " "
Magnesium	6	" " " "
Chloride	7	" " " "
Phosphate	15 mg.	per 100 ml. as phosphorus (by analysis)
pH	7.0	(by analysis)

These values are close to those given for human milk—e.g., Hawk et al. (1947)—except for the calcium, which is normally 15 m.eq. per litre.

Results

Both milks were palatable and taken satisfactorily; one child took the artificial human milk more readily when it was flavoured with 'Marmite.' Both milks showed rapid separation of the cream, especially when heated. After autoclaving at 5 lb. for 15 minutes the cream of the resin-treated milk could be resuspended by shaking: this was, however, impossible with the artificial human milk, which was therefore not heated after addition of the cream.

On our régime the child is given a low-calcium diet based on low-calcium milk. For supplementary carbohydrate 'Farola' is used, because this is a plain semolina to which no calcium has been added. Supplementary iron is also given. No extra vitamin D is allowed, but orange juice or ascorbic acid is given as usual, and marmite as a source of the vitamin-B group. When the serum-calcium level has fallen below 6 m.eq. per litre (12 mg. per 100 ml.), the low-calcium milk is progressively replaced by ordinary cow's milk. Sooner or later spontaneous recovery may be expected, and the infant can return to a normal diet. Since our artificial human milk lacks many ingredients of the natural secretion, it may be unwise to use it as the principal item of diet for more than a month; by this time it should be possible to substitute for it, in part at least, cow's milk.

4 infants with idiopathic hypercalcaemia have now been treated. The 1st received resin-treated cow's milk, the 2nd resin-treated human milk, the 3rd artificial human milk followed by resin-treated cow's milk, and the 4th artificial human milk. In every case there were (1) an improvement in the general well-being of the child within a few days, with increased appetite and cessation of vomiting; (2) a rapid gain in weight, whereas previously weight gain had been very slow or had ceased; and (3) a fall in serum-calcium level, reaching normal

levels in 2-6 weeks. Weight charts are given for each child (fig. 2).

These results must be interpreted with caution because spontaneous recovery is usual. Nevertheless they are encouraging enough to justify the further use of a low-calcium diet in the treatment of this condition.

We thank Dr. J. Apley, Dr. B. D. Corner, and Prof. A. V. Neale for permission to publish the results of treatment in case 1, cases 2 and 3, and case 4 respectively; and Mr. H. Donaldson and Mr. L. Haugh, A.I.M.L.T., for their help in making the special milks.

STERILISATION OF SYRINGES AND NEEDLES

D. STARK MURRAY

B.Sc., M.B. Glasg.

GROUP PATHOLOGIST, KINGSTON HOSPITAL,
 KINGSTON-ON-THAMES

THE sterilisation of syringes and needles for use in hospital wards, theatres, and special departments has become accepted as an essential service and one that is usually organised and controlled by the pathological laboratory. Various techniques have been described, but all leave something to be desired.

At the Kingston Group Laboratory sterilisation in aluminium containers has made the supply of sterile equipment easy and convenient to small hospitals in the group, to general practitioners, and for the use of laboratory staff on domiciliary visits.

Syringes

The traditional ward method of sterilisation by boiling in water covered every type and size of syringe. For hypodermic injections it still appears an adequate and cheap method and will remain so, unless ready-made plastic injectors or cartridge syringes are developed at a very cheap price. There is very little evidence of accidental infections with boiled-up hypodermic syringes and needles; and, if the laboratory-controlled syringe service is not to become unwieldy and expensive, it is probably best to leave the ordinary ward steriliser to deal with many of the hypodermic syringes. We do provide 2-ml. syringes which are used for hypodermic purposes on many occasions, but the Medical Staff Committee decided that the laboratory should not be asked to provide smaller syringes.

The laboratory undertakes this service for two reasons: (1) the laboratory staff can be expected to understand and guarantee the sterility of the syringes; and (2) the laboratory is interested in obtaining good specimens for test purposes, and it is for taking specimens that most syringes are used. Since water, even in minute quantities, may ruin specimens for many tests, the method of sterilisation must be dry, and the use of ovens and the control of their temperatures falls into line with other laboratory procedures.

In most laboratory syringe services the syringe, usually with needle attached, is placed in a glass tube with a cotton-wool plug at the bottom, the whole being wrapped in either 'Cellophane' or kraft paper. This involves having a stock of different sizes of glass tubes, adding one more easily broken object, at about two shillings a time, to the all too easily broken syringe. It involves the cutting of cellophane into appropriate sizes and the wrapping of each syringe separately. In the ward or in the theatre it calls for the laying out of several

syringes which, once removed from their wrapping, are no longer sterile.

An aluminium container (see figure) was therefore devised in which syringes can be stacked in the numbers most likely to be needed, and the needle can be inspected and a syringe selected without interfering with sterility, and which can be safely carried on a ward trolley or in a doctor's car. It takes a moment to fill, stacks easily in the steriliser, and in practice has enormously reduced breakages both of syringes and of other glassware. The present container measures $8\frac{1}{2} \times 8\frac{1}{2} \times 4\frac{1}{2}$ in. and has a handle on top and doors which flap down on either side, lying flat on the table. The syringe-holding clips accommodate on one side 5×2 ml. and 2×5 ml. syringes, and on the other 4×10 ml. and 1×20 ml. In my daily outpatient clinic one container is usually enough. Wards are given a stock according to experience. There appears to be no point in making the containers larger, because it is better for a busy ward to have more than one, and that all should be returned at short intervals for servicing.

The syringes clip on in an upright position but are not disturbed by shaking or if the container is laid on its side. The needle is protected by a glass tube measuring $3 \times \frac{1}{2}$ in. Round the neck of the needle and occluding the glass tube is a small plug of cotton-wool. So long as the wool is there, the needle is sterile; when a syringe is used, the wool is thrown away. After use the syringe is rinsed in cold water and returned to its place, the absence of the cotton-wool indicating that it has been used. The syringes are oiled or coated with silicone. The container is, of course, opened only for as long as is necessary to take out the syringe and closed immediately, and repeated cultures show that no detectable contamination of the interior takes place in ordinary use.

The containers pack very well in the ordinary dry oven and are sterilised by exposure to 160°C for 1 hour. The syringes may be (1) all glass, (2) glass with annealed metal nozzles, of which we use mainly Chance's 'Interchangeable,' or (3) glass with metal ends—e.g., 'Balco'—of which the cement stands up to dry heat. In practice the last-named proves best for ward use, and breakages since the introduction of such syringes in metal containers

The aluminium container with syringes.

have been greatly reduced. All these syringes are Luer fitting. Part of the servicing of the syringe is to test for air leakages, because although modern cements do not run at 160°C they become granular after a time and might not be airtight. They can, of course, be re-cemented. Aluminium containers have not entirely abolished cellophane-wrapped syringes, which may still have a place for certain functions and where only an occasional stand-by syringe is wanted.

In supplying small hospitals and clinics at some distance from a group laboratory these syringe containers appear to be ideal. No attempt has yet been made to calculate whether monetary savings could be made in a group by cutting down on sterilisers or on time spent on sterilising techniques in wards. If made they would be small in relation to the total budget. But in comparison with other syringe-service techniques there is a considerable saving of time, with the result that the output of syringes is greatly increased and the servicing charge per syringe greatly decreased.

Lumbar-puncture Sets

Lumbar puncture is not without its bacteriological hazards, and it is important that the equipment used should be completely sterile. Here again the old technique of boiling the needles and then bringing them to the patient's bed in a container either of water or of spirit was far from perfect. In addition to the lumbar-puncture needle there may also be needed a syringe for injection of a local anaesthetic, a syringe for withdrawal of cerebrospinal fluid, and a manometer. In children's wards the manometer is seldom used, and the needle is usually shorter and finer than for adults.

Accordingly two sets of lumbar-puncture equipment are provided. For the children's ward an aluminium container measuring $8 \times 2 \times 1\frac{1}{4}$ in. is lined with lint and packed with a needle protected by a glass tube, a 2-ml. syringe, and a 10-ml. syringe, the latter with 'Record'-size fitting because no lumbar-puncture needle appears to be made with Luer fitting. After sterilisation the aluminium container is sealed with tape. For adults a container measuring $15 \times 2 \times 1\frac{1}{4}$ in. is packed with manometer, needle, and a 2-ml. syringe and sealed with tape. Wards carry a stock of these containers according to their experienced need, and the doctor doing a lumbar puncture can be sure that he has a complete set of sterile equipment ready to hand. Many manometers are sealed with a cement which does not stand dry heat, and in such a case the container is autoclaved.

Petri-dish Holders

Having had much difficulty with the copper containers for 4-in. glass culture plates which are traditional in every bacteriology department, we decided to try aluminium. To our surprise no supplier whom we asked knew of any firm making such containers, although spun aluminium for cylindrical containers is familiar to every housewife. Later it appeared that others had already tried this idea, and we are now using such a container. In practice it is superior in every way to the familiar copper box. It is seamless, will wear for years as domestic aluminium ware proves, and is cheaper.

Summary

Aluminium containers for syringes are described which make the provision of a sterile syringe service cheaper and simpler. Other aluminium boxes for lumbar-puncture needles and petri dishes are also described.

The prototypes of these boxes were paid for by a grant from the research fund of the South West Metropolitan Regional Hospital Board. Most of the details were worked out by Mr. G. Phillips, chief technician, in conjunction with Mr. W. M. England, of Messrs. R. B. Turner & Co. Ltd., to whom we are indebted for the illustration.

Reviews of Books

Tuberculosis in Childhood and Adolescence

F. J. BENTLEY, M.D., F.R.C.P., D.P.H., senior physician; S. GRZYBOWSKI, M.D., M.R.C.P., senior registrar, High Wood Hospital for Children, Brentwood, Essex; B. BENJAMIN, B.Sc., F.I.A., formerly statistician, London County Council. London: N.A.P.T. 1954. Pp. 259. 30s.

In their detailed account of the course of pulmonary tuberculosis in 1049 children between the ages of 3 and 15 years admitted to the High Wood sanatorium, Essex, during 1942-46, Dr. Bentley and his colleagues have clarified some aspects of the natural history of primary tuberculosis and have considered its epidemiology and incidence. They always have facts to support their views, and their opinions will interest everyone sharing in the care of children with primary pulmonary tuberculosis.

The opening chapter deals with terminology. Then follow chapters on simple primary pulmonary tuberculosis, on segmental lesions, on the influence of age on prognosis, on calcification and secondary infection, and on the management of primary infection. Finally, there are three chapters on chronic (bronchogenic) pulmonary tuberculosis in adolescents and its relation to primary infection. This is in some ways the most important section in the book, because it brings to our attention again one of the most pressing questions in tuberculosis today—that of adolescent phthisis. How often does the chronic disease follow primary infection acquired a short time earlier and incompletely healed, and how much is it due to exogenous reinfection? The importance of this question cannot be exaggerated, for half the children leaving school at 15 years fail to react to tuberculin and most of them are infected within the next few years. The related question—how does bronchogenic tuberculosis arise?—also receives fair treatment.

Tuberculosis is difficult to understand. Few people have the opportunity of seeing the whole picture in a population; the cycle of infection and the possibility of clinical illness spans many years and generations rather than individuals. The authors have tried to overcome the difficulty of dealing with selected material by their "death investigation." But retrospective examination of clinical notes is usually unsatisfactory, and this chapter does not carry the weight of those based on the authors' own data. Even so, it shows that contact clinic work alone, though desirable for other purposes, will not in itself prevent infection or the onset of the serious hæmatogenous or neurological complications.

This authoritative statement of the problem of the primary infection will help to focus attention on the fundamental importance of the primary infection in the natural history of tuberculosis. Production and print are excellent, and the reproduction of the radiographs is far above the usual standard. A book to have and use.

Abilities of Babies

A Study in Mental Measurement. RUTH GRIFFITHS, M.A., PH.D., DIP.ED., F.B.P.S.S. London: University of London Press. 1954. Pp. 229. 20s.

Dr. Griffiths points out that there are three main directions in which man's development differs from that of the higher animals: he achieves the erect posture; this frees the hands, which he uses in manipulative skills; and he learns to speak and to understand speech. "The arresting fact is that all these three aspects of development . . . are achieved by the average baby within the short span of the first fifteen months of his life. This is an enormous achievement . . . which lays the foundations of all that comes afterwards." Dr. Griffiths set out to observe the development of ability in many children under two years old, and finally to test 571 (mostly in infant-welfare centres) in order to establish a scale of development. This sort of thing has been done before, notably by Gesell; but it is all to the good to have a fresh investigation of a difficult subject, with standards based on Kensington instead of Connecticut. By careful investigations, Dr. Griffiths attempts to provide balanced scales of development in five directions—locomotor, personal-social, hearing and speech, hand-and-eye development, and performance (the ability to reason in practical situations or manipulate materials intelligently).

Without using her methods and comparing them with others it is difficult to know how far she has succeeded; but her care, and her own ability to see a situation whole, make an encouraging impression.

How much will this help a doctor trying to decide whether a baby is mentally defective, deaf, or emotionally deprived? Very little, directly, for most doctors (rightly) leave specific testing to the practised expert—though there is nothing in her tests that a physician whose work lay in this field could not master with ease if he took the trouble. On the other hand, the reports of the tests, which in this book are expressed as histograms of the quotients obtained in the five separate groups, should be very interesting. Thus one can see at a glance that although a deaf child has a G.Q. (general quotient) of 82, speech development is only 48, personal-social 75, and locomotor, hand-and-eye, and performance nearly 100. Graphical representation is as telling here as in reports of sugar-tolerance tests or audiograms. Dr. Griffiths does not, however, "claim any great predictive value for the new procedure," which has been in use for too short a time for the babies' test results to be compared with their performance in later childhood.

Mammalian Germ Cells

A Ciba Foundation Symposium. Editor: G. E. W. WOLSTENHOLME, O.B.E., M.B., assisted by MARGARET P. CAMERON, M.A., and JESSIE S. FREEMAN, M.B. London: J. & A. Churchill. 1953. Pp. 302. 30s.

THE twenty-four articles in this symposium provide lucid descriptions, further enhanced by discussions, of pioneer biochemical and endocrinological investigations in the assessment of the fertility of ova and spermatozoa.

The articles are almost equally divided between the two germ-cells and there is a slight preponderance of contributions from this side of the Atlantic. Most of the work is concerned with farm and laboratory animals; only three of the articles deal with human fertility. The fundamental problem is the search for ways of reducing Nature's waste of genetically valuable germ-cells, and the emphasis is on artificial insemination and superovulation. Of particular interest is the possibility of preserving the living germ-cells for long periods at low temperatures.

But all advances have possible drawbacks, and in his foreword Mr. S. J. Folley, D.Sc., F.R.S., gives a clear warning: "The technical advances foreshadowed by the researches reported in this volume are primarily envisaged as applicable to stockbreeding. The fact must be faced that they can also be applied to man, and society will have to consider seriously how best to handle these new possibilities which may be fraught with as much significance and danger of misapplication as the discovery of how to release the energy of the atomic nucleus."

Origins of Psycho-Analysis

Letters to Wilhelm Fliess, Drafts and Notes, 1887-1902. SIGMUND FREUD. Editors: MARIE BONAPARTE; ANNA FREUD; ERNST KRIS. Authorised translation by ERIC MOSBACHER and JAMES STRACHEY. London: Imago Publishing Co. 1954. Pp. 486. 30s.

IN chapter XIII of his *Life of Freud* Ernest Jones has provided so illuminating an account of Freud's relationship with Wilhelm Fliess that most of the novelty of this remarkable correspondence has been anticipated. There is, however, much that rewards the reader interested in the birth-pangs of a revolutionary theory, and the intellectual and emotional crises of a man of genius. The book contains, moreover, drafts of various essays and notes which are significant for the early history of psycho-analysis, as well as Freud's lengthy and sustained, but unfinished, effort to provide a neurophysiological basis for psychology and to furnish us, as its opening sentence put it, "with a psychology which shall be a natural science; its aim, that is, is to represent psychical processes as quantitatively determined states of specifiable material particles"—namely, the neurones. Though it was doomed to failure at that stage of physiological and psychological knowledge, it was almost inevitable that the project should be attempted by a man of Freud's training and that it should contain, hidden behind anatomical and physiological terms, concepts that he

used freely in his subsequent purely psychological writings. The book is supplied with many helpful footnotes, and a concise introduction by Ernst Kris.

Microbiology and Human Progress

MADELEINE PARKER GRANT, PH.D., professor of biology and bacteriology, Sarah Lawrence College, New York: Rinehart. London: Allen & Unwin. 1953. Pp. 718. 48s.

"THIS college text was written for introductory courses in bacteriology . . . for students whose major interests may lie outside the field of science." Such eclectic opportunities in education are rare in our universities, and for this reason the idea deserves sympathetic attention. Professor Grant has read widely and her attempt to present the phenomena of microbiology as illustrations of general biological principles is imaginative and interesting. Almost half the book is devoted to the "microbic foes of man" and this is far less satisfactory. The shorter section on "microbic friends" is also disappointing, for such a book as this would have been a proper place to correct the popular view that bacteriology is the province of the doctor alone.

Surgery for Dental Students

MICHAEL F. A. WOODRUFF, M.D., M.S. Melb., F.R.C.S., professor of surgery, University of Otago. Oxford: Blackwell Scientific Publications. 1954. Pp. 307. 30s.

THIS useful book, based on a series of lectures given by Professor Woodruff when he was a lecturer in dental surgery at the University of Sheffield, is designed for dental students qualifying in this country, and its contents cover the set syllabus. Each subject is dealt with concisely, clearly, and economically, and the text is well illustrated by photographs. These will be very welcome to dental students, who encounter general surgical conditions all too rarely during their training.

The University of Leeds

The First Half-Century. A. N. SHIMMIN, C.B.E., M.A., professor of social science, University of Leeds. Cambridge: University Press. (For the University of Leeds.) 1954. Pp. 230. 21s.

IN this handsome volume Professor Shimmin tells the story of how the university has honoured its motto "And Knowledge shall Increase." In the first part he traces the historical and geographical background to the university's growth and describes its rapid advance during the first fifty years.

The first step was taken in 1831, when the School of Medicine was opened. More than forty years later the Yorkshire College of Science was founded, and in 1887 the two bodies became part of the federal Victoria University, which split into the separate Universities of Manchester, Liverpool, and Leeds in 1903-04. The students are four times as many as in 1904, and it has been hard to keep a balance between science and arts. Professor Shimmin also discusses the problems of student welfare and the relationship of the city with the university, and in the second part of the book he describes the trend of present-day teaching and research in each faculty. Maurice de Saumarez, the head of the department of fine art, has contributed graceful pen and wash drawings.

Arthur Rendle Short: *Surgeon and Christian* (London: Intersarsity Fellowship. 1954. Pp. 208. 8s. 6d.).—It is but eight months since Rendle Short died, and this interval does not allow of the effective critical appraisal he deserved. In this biography Mr. W. Melville Capper and Mr. Douglas Johnson, seeking to perpetuate the main message of his life and to throw into relief the principles which inspired it, give a good deal of space to his work for the Christian Brethren of Bristol and the West Country, but there are also interesting sections on his experiences as an undergraduate student, a young doctor, and a surgeon on the staff of a teaching hospital. Here much of the material is autobiographical, including his characteristic description of the day he thought that he had bungled hopelessly his final F.R.C.S. examination. "Filled with gloom and despair I betook myself to a scientific library and got down a copy of the *Quarterly Journal of the Geological Society* containing Vaughan's paper on the Carboniferous. It was immensely comforting."

The **SAFE SELECTIVE** wide-range Antibiotic for Children

PAEDIATRIC SUSPENSION

- ★ Administered Orally — Delightfully flavoured
- ★ Effective against the most common pathogenic organisms — Staphylococcus, Streptococcus, Pneumococcus
- ★ Effective against resistant strains
- ★ **SAFE** — no alteration in normal blood picture
- ★ 100 mg. in each 5 c.c. (large teaspoonful)
- ★ Dose $\frac{1}{2}$ teaspoonful per stone bodyweight every 6 hours.

A NEW SAFE ORAL Antibiotic against MOST of the common infections of childhood.

Beyond Spens

THE Government's decision to find another £3¹/₄ million a year for hospital doctors was surprising. At a time when taxation is too heavy, when wage claims are strongly discouraged, and when hospitals are being asked to cut their expenditure, it cannot have been convenient to add so large a sum to the incomes of a small number of people who, in the eyes of the public, are already well off. The decision was made for two reasons: first, because the Danckwerts award tipped the balance so far in favour of general practice that recruitment of able young doctors to the specialties was endangered; and, secondly, because some members of the Cabinet felt that consultants had not had a fair deal. The unfairness, of course, lies in the fact that, though the Government of the day accepted the reports of both the medical Spens Committees—on the remuneration of general practitioners and on the remuneration of hospital doctors—quite different "betterment factors" have been applied to practitioners and to consultants in translating the Spens 1939 figures into post-war money. Under the Danckwerts award practitioners gained 100% betterment; and though this was not distributed equally among them, and was conditional on a reduction in the size of the larger lists, their allowance for changes in the cost of living became far higher than the betterment factor of about 20% which was given to hospital staffs. Thus nobody could pretend that the financial recommendations of the second Spens Committee had really been fulfilled, and in making amends to the tune of £3¹/₄ million the Government still fall short of fulfilling them. On the other hand, from the time that consultants accepted their contracts in 1949 there has been no legal obligation on the Government to revise the terms of these contracts; and if, as some suggest, hospital consultants are now to say "thank you for nothing" and press implacably for "every penny of Spens," they should remember that moral obligations are seldom as precisely assessable as legal ones. A moral claim—that is to say, a claim to what fair-minded people will think proper—differs from a legal claim in that the field of inquiry is larger.

The first Spens Committee was asked to consider "what ought to be the range of total professional income of a registered medical practitioner in any publicly organised service of general medical practice," and it concluded that before the war too many general practitioners had too low an income. Accordingly it recommended a range of remuneration which it hoped would increase the financial attractions of general medical practice both as against other professions and as against other branches of medicine; and, thanks to the Danckwerts award, this hope has

now been fulfilled. The second Spens Committee was asked to consider "what ought to be the range of total professional remuneration of registered medical practitioners engaged in the different branches of consultant and specialist practice in any publicly organised hospital or specialist service." Though it wanted to raise the financial status of men and women in training, it was concerned to maintain, rather than improve, the situation of the specialist or consultant, and its proposals were designed to give him, in relation to other people, a position such as he held before the war. On a general view, it is arguable that this object, too, has been attained¹—at least for the part-time consultant, whose opportunities for private practice remain greater than was expected. The relatively unsatisfactory position of the whole-time consultant might best be dealt with, not by any general raising of consultant remuneration but by applying the Spens recommendation about expenses to the whole-timer and by allowing him to take fees for domiciliary consultations—a change which is demonstrably desirable for the proper working of the service.²

The post-war redistribution of national income in favour of the wage-earner, and the taxation by which it is maintained, have combined with rising prices to hit the salaried middle classes; and few among them can afford the amenities of 1939, at any rate if they are paying for the private education of children. Hence the adequacy of doctors' remuneration cannot be judged simply by whether they feel that they are comfortably off. The ultimate test is whether the main purpose of the Spens proposals has been achieved: do enough recruits of the right type still apply to take up medicine, and do enough doctors of the right type think it worth their while to train for a specialty? Certainly the public will be ill served if doctors cannot maintain a decent standard of life or if they are preoccupied with getting money or making ends meet. They will be even worse served if too many intelligent boys and girls decide that medicine is too unremunerative for them to take up, or if too many intelligent doctors decide that they cannot afford to be anything but general practitioners. In so far as it has reason to believe that any of these things are happening or likely to happen the profession can reasonably urge that scales of payment should be altered. But whatever claims it makes for revision of remuneration in the National Health Service should arise from the requirements of that service at the time of the claim. The public interest is a sounder basis for negotiation than the litigious reiteration of former rights whose present validity is in doubt.

The two medical Spens reports were brilliant and influential documents, and the one on consultants and specialists showed exceptional insight and foresight. It abolished the state of affairs by which many doctors could not afford to train as specialists unless they had private means. It gave the same basic pay to consultants in London teaching hospitals and in the district hospitals of the remotest region, and to those in the oldest and in the newest specialties. It introduced a novel system by which, while age and service had their due, allowance was made for out-

1. Central Consultants and Specialists Committee, Bulletin no. 3; pp. 4 and 7.
2. See *Lancet*, Jan. 23, 1954, p. 210.; Feb. 13, p. 366; Feb. 20, p. 412.

standing merit. At a time of egalitarian revolution, it insisted that the range of remuneration should remain wide. And finally it introduced the principle that experts working in a public service should have the kind of livelihood they could earn outside it—a principle repugnant to many administrators but profoundly important if public services are to be more than second-rate. Nevertheless, though in all this “consultant Spens” justifies its description as a charter, it scarcely qualifies as an infallible work of revelation. In the first place (assuming equal betterment over 1939 money values) it made the remuneration of specialists so superior to that of practitioners that it defeated the intention of the previous Spens Committee, which wanted to make general practice “sufficiently attractive to prevent all the abler men endeavouring to enter specialist practice.” Equally serious, however, was its failure to make any distinction between consultants and specialists, and its consequent assumption that all the doctors in a hospital were either consultants or were training to become consultants. As soon as the Ministry of Health began to consider the offer of contracts, it could not but observe that in many departments of medicine—notably in psychiatry, pathology, venereal diseases, and tuberculosis—there are not a few doctors whose continued services are very necessary to the hospital but to whom their colleagues turn as specialists rather than as consultants. To meet this difficulty the Ministry, with the reluctant acquiescence of the profession, made a major departure from the Spens charter and invented the grades of senior hospital medical officer (S.H.M.O.) and junior hospital medical officer, tenable only in certain specialties. Up to now the representatives of the profession have been unwilling to agree to appointments to this grade in the main departments of medicine; for, with good reason, they fear the possibility that administrators, intent on saving money, may see in such lesser appointments a means of economising on consultants. But here again, when it comes to running the hospitals, we come up against hard facts. If, in order to prevent future disappointment, the number of young men allowed to train for consultant posts is henceforward to be strictly related to the number of consultant posts expected to fall vacant, there will no longer be enough trainees in the hospitals to ensure that the necessary medical and surgical work gets done. Much essential work is undertaken by those senior registrars who, because they have not yet secured posts as consultants or S.H.M.O.s, are now described as redundant. The truth is that few if any of these are really redundant; and, if our existing system has no place for them, we shall evidently have to make such alterations in the system as will enable them to go on using their skill to advantage. This is as necessary for the sake of the hospitals as it is for the sake of the registrars themselves, who were encouraged by the Ministry and the profession to train themselves for consultant posts which have not materialised. Their plight has become a standing reproach to us all.

What seems to be needed to restore health to the hospital medical service is that all parties should agree to go back to the point where the Spens Committee (as we can now see) failed in prescience—the point at which it lumped consultants and specialists

together. In our opinion the proper title for a person who has completed his training in a specialty, or has spent some years in specialised activities, is that of specialist, and we see no reason why appointment as a specialist (working under some degree of supervision by a consultant) should not be the route by which consultant rank is normally approached. The transference of S.H.M.O.s to the new grade would not only give them a more suitable title but also rescue them from a backwater where no current flows—a backwater from which very few have been able to regain the main stream. To the registrars who have been miscalled redundant, appointment as specialists would give time to prove their capacity to become consultants, or at the worst it would enable them to continue (as members of a team though not at its head) the kind of work they have chosen. To achieve these ends without jeopardising the position it has to defend, the Joint Consultants Committee will doubtless have to make conditions: it will need power, for example, to control, with the Ministry, the numerical relationship of specialist and consultant posts. But we feel sure that better and more rational arrangements can be made for hospital medical staff—provided consultants are ready to think beyond the Spens report and to follow the spirit rather than the letter of that famous text.

Renin

ALMOST sixty years ago TIGERSTEDT and BERGMAN¹ showed that the injection of a saline extract of fresh rabbit kidney into normal rabbits caused a rise of arterial blood-pressure. They recognised that with repeated injections the pressor effect diminished and eventually ceased—a feature termed tachyphylaxis. Despite a vast amount of investigation the significance of the renal pressor agent, known as renin, in human hypertensive disease is still far from certain. Renin is a protein enzyme obtained from renal cortex which reacts with its substrate, hypertensinogen (a plasma alpha-globulin), to form a substance of smaller molecular weight known as hypertensin. This is probably a polypeptide and is the active pressor agent, renin being inactive in the absence of its substrate. Hypertensin is labile and is rapidly destroyed and inactivated by a plasma enzyme known as hypertensinase. SKEGGS et al.² have recently shown that the chemical reactions involved are complex. By a counter-current distribution process they have separated hypertensin into two polypeptide fractions, which they term hypertensin I and II. The former is rapidly converted into the latter by another plasma enzyme. Both are active pressor agents and caused very considerable increases of both systolic and diastolic blood-pressure when injected intravenously in volunteers.

PICKERING and PRINZMETAL³ showed that the blood-pressure of rabbits starts to increase about thirty seconds after an injection of renin, the highest pressure being reached about two minutes after the injection; the pressor effect usually lasts thirty minutes or longer. Despite the property of tachy-

phylaxis, BLACKET et al.⁴ have maintained hypertension in rabbits for as long as two weeks by infusing renin. The cardiac output is somewhat reduced after injections of hypertensin in man,^{5 6} the pressor effect being entirely due to peripheral vasoconstriction. The glomerular filtration-rate tends to rise and renal blood-flow falls considerably⁷; these differential effects are usually held to indicate constriction of the efferent glomerular arteriole. Such circulatory and renal haemodynamic findings are similar to those in essential hypertension,⁸ but unlike those in acute glomerulonephritis⁹ where afferent arteriolar constriction is thought to occur. DANIEL et al.¹⁰ have further investigated the effects of renin on the renal circulation of the rabbit by an angiographic technique. Angiograms taken shortly after the peak of the pressor response showed constriction of the smaller intrarenal arteries and increased renal circulation-time. In half the animals the ischaemia involved chiefly the peripheral cortex; in the rest it was more generalised. Some renal vasoconstriction was still present shortly after the blood-pressure had returned to normal. It seems very unlikely that renin is directly concerned in the aetiology of essential hypertension in man. HAMILTON et al.¹¹ have found that the condition we speak of as essential hypertension cannot be strictly defined, there being a continuous variation of blood-pressure levels in any group of selected age and sex, with no evidence of any natural division between hypertensive and normotensive people. HAYNES et al.¹² found no significant difference in the content of renin in blood obtained by catheterisation of the renal vein in patients with hypertension of varied origin and in control normotensive patients. A humoral mechanism is perhaps most likely in hypertension secondary to unilateral renal disease—usually chronic pyelonephritis^{13 14}—but the part played by renin has not been exactly defined either in this clinical disorder or in experimental hypertension secondary to renal ischaemia. In particular we are completely ignorant of the reason why some cases of chronic pyelonephritis are associated with hypertension while some are not.¹⁵

Renin has been shown to have a distinct diuretic effect in the rabbit and the rat—an effect that has not been demonstrated unequivocally in other species. PICKERING and PRINZMETAL¹⁶ showed that in rabbits injection of renin produced extreme diuresis, with increased loss of sodium and chloride, associated with proteinuria amounting to 100 mg. per 100 ml. ADDIS et al.¹⁷ described similar findings in the rat, but the proteinuria was more severe. Inactivation of renin

with respect to the pressor response led to loss of capacity to produce proteinuria. In the adrenalectomised animal the production of proteinuria was almost abolished. HUGHES JONES et al.¹⁸ showed that hypertensin was similarly active in causing polyuria in rabbits. The diuresis was shown to be due to inhibition of tubular capacity selectively to reabsorb sodium, chloride, and water. The sodium-chloride content of the urine approximated to that of plasma—which is typical of osmotic diuresis. It seemed most improbable that the diuretic effect was directly due to the pressor response. The polyuria was in some cases greatest when the blood-pressure had fallen to normal levels, and when the changes of the condition of glomerular filtration (shown by a raised filtration fraction) had disappeared. CROXATTO et al.¹⁹ have further investigated this diuretic effect in rats. Adrenalectomy or hypophysectomy inhibited the response, but selective extirpation of the adrenal medulla was without effect. The administration of either cortisone or deoxycortone restored the response to normal. The greatest polyuria observed was in an animal which excreted in one day urine amounting to 42% of its body-weight. It seemed in general that sodium depletion tended to inhibit, and sodium excess to increase, the diuretic response. Since the dose of renin necessary to produce diuresis is greater than the effective pressor dose, it might be unsafe to extend similar observations to man. The fact that deoxycortone restored the diuretic response in adrenalectomised animals is of especial interest. It is now well known that cortisone restores the impaired diuretic response to ingested water in Addison's disease, whereas deoxycortone is inactive in this respect. A recent report²⁰ on the administration of the natural salt-retaining hormone of the adrenal cortex (aldosterone or electrocortin) in the treatment of Addison's disease suggests that this steroid is also inactive in restoring the diuretic response.

Encephalitis Viruses

In the past thirty years we have learnt a good deal about the relationship between the many different viruses of epidemic encephalitis. Between 1915 and 1926 world-wide outbreaks of von Economo's disease appeared suddenly and then faded, leaving behind a residue of postencephalitic parkinsonism. The aetiological agent of von Economo's disease was never discovered, but its winter epidemic incidence differentiates it from newer forms of epidemic encephalitis which have appeared or been recognised since. The newer forms are usually localised to a particular geographic area which may appear to enlarge as investigations uncover more infected areas. The encephalitides include Australian X disease, recently identified with Murray Valley encephalitis²¹; the closely related Japanese B encephalitis, the virus of which has been responsible for outbreaks in Japan, China, Korea, and Malaya; the encephalitides of the

American continents (St. Louis, Eastern, Western, and Venezuelan equine); Russian Far Eastern encephalitis, reported from Russia and Siberia and recently from Czechoslovakia and Jugoslavia; and the closely related louping-ill, an encephalitis of sheep, rarely of man, in Scotland and the north of England, and our only representative of this group. The infectious agents of these diseases have some properties in common. They all characteristically produce summer outbreaks; all are small viruses with an extraordinarily wide natural and experimental host-range; and all are transmitted by biting arthropods. The localised geographic distribution of these infections, in contrast to the world-wide distribution of measles, influenza, and poliomyelitis, shows that man does not form the staple diet of the encephalitis viruses. Man is, in fact, a wholly dispensable link in a chain of infection which is made up in different cases of such widely different creatures as monkeys, horses, cattle, birds, mosquitoes, and ticks.

The relationship of the encephalitis viruses to one another and to certain tropical viruses, such as West Nile, Semliki Forest, and Bunyamwera viruses, has lately been investigated. OLITSKY²² has suggested that many of these viruses may have had a common ancestor whose behaviour in different areas was conditioned by local insect vectors or animal and bird reservoirs of infection, and he cites the typhus group of diseases as a useful analogy. The demonstration of viral hæmagglutinins in tissues infected with some neurotropic viruses²³ and subsequently with various arthropod-borne viruses^{24 25} suggested a new weapon for research into these diseases. CASALS and BROWN²⁶ have taken full advantage of this method, and by modifying the technique for extracting viral hæmagglutinins they have been able to study hæmagglutination by many different arthropod-borne viruses. They find that these viruses can be divided into two groups, on the basis of the temperature and pH required for the agglutination reaction. Group A, which require 37°C and pH 6.4, comprise Eastern, Western, and Venezuelan encephalitis and Sindbis, a virus recently isolated in Egypt. Group B, which agglutinate at 4°C or 22°C and pH 7.0, comprise dengue types 1 and 2, Ilhéus, Japanese B, Ntaya, St. Louis, Uganda S, West Nile, and yellow-fever viruses. Serological tests by the agglutination-inhibition reaction have confirmed the groupings; there were considerable cross-reactions among viruses within the A and B groups but none between sera of one group and viruses of the other. Indirect evidence also suggests that Semliki Forest virus belongs to group A and Russian Far Eastern and louping-ill viruses to group B. Earlier serological studies by neutralisation and complement-fixation tests had shown some cross-reactions among these viruses; and SMITHBURN²⁷ has now completed an intensive study of this subject. He has carried out cross-neutralisation tests in mice with most of the arthropod-borne viruses investigated by his colleagues,²⁶ and has found some new relationships not hitherto revealed by neutralisation tests. His findings

agree in general with those of CASALS and BROWN, although the groupings shown by agglutination-inhibition tests are much clearer than those with neutralisation tests.

These most important studies may open the way to an understanding of how the different viruses have evolved from common ancestors, and of the factors underlying host differences and variations in virus pathogenicity in different areas. Perhaps, too, once these viruses have been neatly classified they may become more amenable to the efforts of those who are trying to domesticate them.

Annotations

BIRTHDAY HONOURS

ALL who have heard Sir Russell Brain's speeches and addresses in the past few years will have enjoyed their individual mixture of freshness and wisdom, and the remarkable range of his understanding. They will join with the fellows of his college in welcoming the new honour bestowed on a president who has the rare gift of bringing philosophy into affairs. Of the new knighthoods only one is conferred on a member of our profession in this country; but the choice is a most happy one, for Mr. R. C. Brock is one of those men who make medical history as well as writing about it. With his cardiological colleagues at Guy's he has helped to turn the possible into the practicable and the practicable into the useful, and in so doing has shown himself one of the most able exponents of one of the most progressive parts of surgery. It is a pleasure also to record the knighthoods conferred on two Australian colleagues, Dr. A. P. Murphy, F.R.A.C.P., and Mr. H. H. Schlink, and the various appointments to Orders which are set out on p. 1287.

RECOVERY HOMES

NOWADAYS patients well enough to leave hospital are not necessarily well enough—as the almoners have lately pointed out¹—to go to convalescent homes; for such homes are not staffed or equipped to look after people who need any nursing or other special care. The convalescent homes committee of the King's Fund, with Sir Henry Tidy as chairman, have been looking into the "recovery homes" which some hospitals maintain, in order to decide what value they might have for the hospital service as a whole.² The committee thought at the outset that some existing convalescent homes might be adapted to take patients in the earlier stages of recovery, but experience has convinced them that it would not do. Most homes of the kind are not structurally suitable, nursing staff would be hard to get, and maintenance costs would go up. Recovery homes are set up and maintained by hospitals, which can of course supply the nurses. Only a few of the Metropolitan hospitals—and none of the London teaching schools—have recovery homes; but several large general hospitals elsewhere have established them, to relieve pressure on their beds. The Astley Ainslie Institution, attached to the Royal Infirmary at Edinburgh, the pattern recovery home of the country, defines itself as providing accommodation

"for patients in whom the disease has definitely begun to abate, or the risk of complications after operation is only slight, so that with proper care and nursing the patient is likely to progress to recovery."

The committee have adopted this definition. They visited ten hospitals and their country recovery homes,

and found the hospital authorities enthusiastic about the value of the plan. With one exception (a London hospital, far from country places) the homes were within a dozen miles of their parent hospitals.

All the authorities agreed that the home should be an integral part of the hospital, which supplies stores, food, drugs, and general services. The patients are visited at regular convenient intervals by senior residents and members of the consulting staff. At the homes which are over twelve miles from the parent hospital, the hospital arranges for a general practitioner to be on call in an emergency. About half the nursing staff are State-registered, and more or less permanent; student nurses take a turn of duty there, and find it stimulating, partly because of the rapid turnover of patients and partly because the trained staff have time to teach. The patients need the same skilled nursing care, and the same medical attention, as they would be getting in hospital, and the home provides it. Pre-students are sometimes allowed to do minor offices in the home; and this seems to be the one place where such young people may safely be allowed to come into contact with patients. (Such homes may therefore prove good training places for nursing cadets.) No operating-theatre or X-ray or other expensive equipment is needed, for these are all provided at the parent hospital.

The patients most suitable for admission are those with moderately severe medical, surgical, or gynaecological conditions who need 12-15 days in hospital and about the same time in the home. Long-term orthopaedic, geriatric, or chronic cases should be sent elsewhere, for they quickly block beds and change the whole spirit and purpose of the home. The hopeful name, the change of scene, and the rapid turnover in population all have a part to play in helping patients to recover quickly, and go back home: at the end of their stay they should not need convalescent care as well. If patients are properly selected, only about 30% of the medical, surgical, and gynaecological beds will be found to be discharging their occupants to the home. A common fear among hospital authorities who have not set up such homes is that the increased turnover in the wards may throw too much extra work on the nursing staff. In fact there have been no complaints of overwork from ward staff; and even where the rate of turnover is at its highest the addition of one extra nurse to the ward has been enough to cope with it.

Hospitals usually buy country houses to convert into recovery homes. These commonly have good grounds in which patients can refresh themselves, and which will also provide a large part of the vegetables and fruit needed. One such house was converted at a cost of £800 per bed, and another at a cost of only £470 per bed. The cost of maintaining a patient in a recovery home is less than half the cost of maintaining him in hospital, so the total cost per patient falls. Though hospital waiting-lists are reduced, and turnover increased, the committee could not find any evidence of a recognisable increase in the maintenance costs of a parent hospital as a result of having a recovery home. These findings should reassure hospital authorities longing for a recovery home but fearing to take the plunge; it should also wake a spirit of adventure in those who have not so far contemplated the possibility.

NEEDLE BIOPSY OF LUNG

THE investigation of a case in which radiography has shown a pulmonary lesion often reaches an impasse, with no clue to the diagnosis from bronchoscopy and bronchography and examination of sputum or bronchial secretions for malignant cells, fungi, and tubercle bacilli. In these circumstances needle biopsy under fluoroscopic control is tempting; but, because of the dangers of air-embolism, hæmorrhage, and the dissemination of

infected material or neoplastic tissue, most physicians prefer to transfer the case to the surgeon for exploratory thoracotomy. Dutra and Geraci¹ recommend needle biopsy of the lung for a limited class of cases: the clinical evidence should point to an incurable malignant condition, the lesion should be peripheral, and attempts by other methods to clinch the diagnosis should have failed. The area of skin nearest the mass is found by fluoroscopy and marked, and the biopsy is done with a Vim-Silverman needle. They consider that needle biopsy should not be done if surgical treatment seems feasible—a point that is emphasised by one of their cases in which an implant of neoplastic cells in the needle track led to a subcutaneous tumour.

ADRENAL HYPERPLASIA AND NEOPLASIA

IN the adrenal glands either a tumour (usually unilateral) or hyperplasia (which is bilateral) can produce virilism.² The abnormality is associated with a large excretion of 17-ketosteroids in the urine. When congenital it produces macrogenitosomia præcox in the male and pseudo-hermaphroditism in the female; there is often also a defect in the regulation of salt metabolism.^{3,4} If the abnormality arises after the external genitalia have developed in the fourth month of foetal life, then in the female the result is simply virilism, with hirsutism and enlargement of the clitoris. The male still shows macrogenitosomia if the lesion is prepubertal; since the adrenals are responsible for the abnormal output of hormone, the testes remain infantile, and in this way the disorder can be distinguished from other types of precocious puberty in the male. It is obviously difficult to recognise the abnormality in the male after puberty.

In congenital cases hyperplasia is the usual lesion; but otherwise a tumour—not necessarily malignant—is more common than hyperplasia, particularly before puberty. In either case the pattern of steroids secreted by the adrenal is abnormal.^{5,6} Jailer et al.⁷ have ably reviewed the effect of large doses of cortisone on the high output of 17-ketosteroids. From their own wide experience, and from the results reported by others, they show that cases of hyperplasia respond with a fall in 17-ketosteroids whereas cases of tumour do not. Cortisone usually produces a remission in virilism associated with adrenal hyperplasia, presumably by inhibiting the pituitary; but tumours of the adrenal seem to be independent of pituitary control and operation is the only treatment.

In Cushing's syndrome the secretion of the normal adrenal hormone is excessive; but there may be an abnormal pattern, and virilism and Cushing's syndrome can occur together. Although the results were less clear-cut than in virilism—the excretion of 17-ketosteroids in Cushing's syndrome is not necessarily very high—Jailer et al. found that the "cortisone test" may also be useful in differentiating tumour and hyperplasia of the adrenal in Cushing's syndrome. A tumour requires a unilateral operation. For hyperplasia producing Cushing's syndrome bilateral subtotal adrenalectomy may be required if the condition is progressive and disabling; destruction of the pituitary has also been tried successfully.

These are uncommon diseases. Virilism must be distinguished from simple hirsuties, and adrenal virilism

from that produced by hypothalamic,⁸ pituitary, and gonadal disorders.² The diagnosis of Cushing's syndrome requires evidence of adrenal over-activity; and many women with obesity, hirsuties, hypertension, and diabetes have not got this syndrome. But the few unfortunate patients who have adrenal disorders can often be helped.

TOWARDS CLEAN AIR

For centuries private citizens and public committees have talked of smoke abatement. The outlook, however, has so steadily darkened that the "six counties overhung with smoke" which William Morris found such difficulty in forgetting, are now indistinguishable from most of their neighbours. The National Smoke Abatement Society (N.S.A.S.) in a memorandum¹⁰ addressed to the Committee on Air Pollution (the Beaver Committee), say that the reason effective action has never been taken is because there has never been an informed determined public demand for it. The London fog disaster of 1952, however, sharply increased interest in air pollution; and people are readier than they have ever been to attend to its causes and press for remedies.

The society believe the subject to be of such importance that smoke prevention should be among the first factors considered when the use of fuels is under discussion; and that all fuel policies, developments, and propaganda which are not in the interests of smoke prevention (such as propaganda for the overnight use of bituminous slacks on domestic fires) should not be countenanced. No change in legislation would be needed to achieve this—only a change in outlook among those responsible for fuel policies. Many other preventive measures could be applied under the existing laws: coal could be better cleaned, so that it emitted less sulphur dioxide and grit when it was burned; different types of plant could use appropriate grades of coal for smoke prevention, and the quality supplied could be consistent; stokers could be better trained; fuel-burning plant could be better maintained and managed, and the rate of modernising plant could be hastened; both in industry and in the home the use of gas and electricity could be extended; and the replacement of raw coal with solid smokeless fuel might proceed much faster than it does. Some 37 million tons of smokeless fuel is produced annually in Great Britain, of which only 5 million tons is available for domestic purposes. It has been estimated that—partly by increased production and partly by withdrawals from other markets—10 million tons could be made available for domestic use by 1957, and 15 million tons by 1962. Meanwhile the society urge that available supplies of smokeless fuels should be sent to areas which will benefit most from their use—such as smokeless zones.

Naturally research is needed, not only to develop new processes for the production of smokeless fuel, but on such pollution problems as the removal of sulphur dioxide, grit, and dust from flue gases; and on the pollution caused by steel and clay industries, coke ovens, cement manufacture, lime-burning, chemical processes, and road-vehicle exhausts. The last is an up-and-coming nuisance which we should do well to scotch in time. Diesel fumes thicken on our roads; and the plan to exchange London's 1800 clean and silent trolleybuses for diesel-engine motor-buses has already caused many protests.¹¹

Again, the N.S.A.S. think that local authorities proposing schemes for reducing air pollution get too

little encouragement. Initiative of this kind, they say, should be not only approved but stimulated by the Government; for too many local authorities are still inactive.

The law about smoke has remained substantially the same for three-quarters of a century, and is almost entirely of the too-late variety (in the sense that action can only be taken after a nuisance has been caused). The society suggest that new legislation should not only give local authorities better powers for setting up smokeless zones but should enable them to proceed against manufacturers whose chimney emissions exceed prescribed standards. It should also oblige manufacturers who are putting in new fuel-burning plant to have their plans approved beforehand by the local authority. Moreover, all boiler-men and furnace-men should be required to hold a certificate of proficiency; and local authorities should be obliged to employ only fully qualified smoke inspectors. Finally, the society suggest, the installation in houses or hotels of grates which cannot burn smokeless fuel should be prohibited.

The society, in their steady education of the public in this matter, have done good work and done it on a very small budget. They are fully justified in suggesting that they deserve a Government grant towards it, for no agency is better placed for creating the informed public opinion which alone can lift the cloud from us.

RECURRENT PANCREATITIS

PANCREATITIS is apparently commoner in North America than here. Several accounts of this disease have appeared in the U.S.A. during the last few years¹⁻³; and at the recent meeting in London of the American College of Surgeons Prof. Walter C. MacKenzie described his extensive experience of it in Canada.⁴ According to Phillips,³ it is usually a chronic relapsing disorder in middle-aged alcoholic men. There is a fairly characteristic pattern of attacks of upper abdominal pain, recurring on average three or four times a year, which are often precipitated by alcoholic or dietary indiscretion or by worry or fatigue.² The attack may be mild, lasting only a few hours, or of the severe "acute hæmorrhagic" type that continues for several days. Vomiting is usual and there may be mild diarrhoea; pyrexia is seldom pronounced; loss of weight during the attack may be severe. In uncomplicated cases the patients are free of symptoms between attacks. Eventually fibrosis may lead to cyst formation or to calcification, which may be localised or diffuse. Occasionally severe fibrosis may produce bile-duct obstruction, but this is probably rare.

Confirmation of the diagnosis by clinical tests is often difficult. Radiographic evidence of pancreatic calcification, the presence of steatorrhœa, creatorrhœa, or glycosuria, or a raised serum amylase or lipase level are highly significant. But such evidence is to be expected only in severe attacks or when repeated episodes have considerably damaged the gland. In mild attacks and between bouts, investigations often yield negative results. Examination of the duodenal contents after administration of secretin has been recommended, but this test is tedious and difficult and the results are inconstant. With pancreatitis, as with so many diseases, the case-history is often a better guide than a group of tests. The acute episode is best treated conservatively with analgesics (but not morphine) and antibiotics. Atropine or, better, 'Probanthine' is given to decrease gastric and pancreatic secretion, and to relax the

sphincter of Oddi; in an acute attack withdrawal of secretion through a Ryle's tube is valuable. Operation between attacks may be necessary if cysts are present, or to deal with associated biliary-tract infection. In addition, thoracolumbar sympathectomy, vagotomy, sphincterotomy, and pancreatectomy—alone or in various combinations—have all been tried, and "beneficial results are reported after each procedure."³

The cause of pancreatitis is still undetermined. Opie⁵ suggested that it is due to reflux of infected bile along the pancreatic duct, and this view has been widely held. There are, however, several objections to it, the chief of which is that pancreatitis without associated biliary-tract disease is not rare. Some observers^{3, 6} have, in fact, claimed that biliary disease, when present, is the result of the pancreatitis. Virus infections, such as mumps and virus pneumonia, may produce isolated acute attacks, but seem unlikely to be responsible for recurrent episodes. Probably one clue to aetiology lies in the high incidence of chronic alcoholism among patients with recurrent pancreatitis. Possibly chronic alcoholic gastroduodenitis produces oedema round the duodenal papilla, with consequent obstruction to the flow of pancreatic juice, followed by stasis and infection within the ducts.³ Klatskin and Gordon,⁷ in a study of familial essential hyperlipæmia with associated pancreatitis, found evidence suggesting that the former condition preceded and might cause the latter. But the majority of patients with recurrent pancreatitis show no sign of hyperlipæmia; and Professor MacKenzie believes that the essential factor is the development of a vascular lesion while the gland is under a pronounced secretory stimulus.

PROPHYLAXIS OF MEASLES COMPLICATIONS

In the U.S.A. gamma-globulin for the prophylaxis of measles in contacts has been obtainable until recently at the corner drug-store; but in the last year it has been temporarily withdrawn from the market owing to its wide use in the prophylaxis of poliomyelitis. This has had the effect of focusing attention on prevention of the bacterial complications of the disease by chemotherapy.

For some years the usual practice has been to give sulphonamides, or sometimes penicillin, to young children with measles for five or six days after the appearance of the rash, as a protective "umbrella" against pneumonia, otitis media, and other bacterial complications; and this has proved strikingly successful.⁸⁻¹¹ Karelitz and his associates¹² at the Willard Parker Hospital, New York, have now tried the effect of a single injection of the repository form of benzathine penicillin in 61 children with measles, and only 2 developed bacterial complications. The controls were 67 patients who received on admission four daily injections of aqueous procaine penicillin 300,000 units, 47 who received aqueous penicillin 600,000 units on alternate days for three doses, and an untreated series of 41 children. These groups were formed by alternate allocation of patients on admission, except that those with complications already present were alternated in the penicillin groups, which were thus fairly severely weighted. No bacterial complications occurred after admission to hospital in the procaine penicillin groups, but of the

untreated controls 28% had complications—mainly pneumonia. Karelitz et al. suggest that it is now clear that most bacterial complications of measles can be avoided by timely antibiotic therapy; and aqueous procaine penicillin, being relatively painless, has advantages over other depot penicillins. In this country quite satisfactory prevention of bacterial complications can still be obtained by the simpler and cheaper method of sulphonamide prophylaxis. This is one of the few forms—if not the only form—of routine sulphonamide prophylaxis that can be generally recommended.

"ARTIFICIAL HIBERNATION" IN THE WOUNDED

Not uncommonly severe injury is followed by a vasovagal reaction, which may possibly aid survival. Such a reaction can be prolonged by means of "artificial hibernation," which Huguenard¹ has defined as controlled inhibition of the autonomic nervous system with lowered metabolism, muscular relaxation, and twilight-sleep. Laborit and other French workers have brought about this "physiological alienation," in order to prevent or treat shock,² by means of various drugs, including a "lytic" mixture of chlorpromazine hydrochloride ('Largactil'), promethazine hydrochloride ('Phenergan'), pethidine, and diethazine hydrochloride ('Diparcol').

Last year, after visiting the front in Indo-China, Laborit and Huguenard³ suggested that such a mixture might usefully be administered to the wounded at any stage of evacuation behind the regimental aid-post. In the past year this method has been applied to nearly 250 casualties; and Chippaux et al.⁴ compare the results with those in a group of similar casualties treated by orthodox methods. They conclude that in 10 of 51 severely injured patients who died after orthodox treatment, the outcome might have been different if the lytic mixture had been given. This technique, they say, should be practised only at the place where full resuscitation and surgical treatment are to be carried out, after diagnosis and a decision about operation. The method does not reduce the amount of blood required for replacement, and its use should be preceded by full resuscitation. In Indo-China the conditions most likely to be benefited seemed to be severe burns, shock resistant to transfusion, blast injuries, and hyperpyrexia. The advantages are said to include easier anaesthesia with smaller doses, prevention of operation shock, and greater comfort in the early postoperative period. Against these must be set the difficulties of applying the method in the forward area, where the treatment of the most severe battle injuries is best undertaken; the need to observe the comatose patient closely for thirty-six to forty-eight hours; and, in the tropics, the necessity for air-conditioned accommodation.

These observations do not finally decide the value of "artificial hibernation" in the field; but at present this seems very limited.

MESSRS. CHRISTIE

UNDER the heading of "In England Now" last week, a correspondent told the story of some people living in a caravan who owned a picture by Turner and were supposed to have had an offer of £6000 for it from a representative of Christie's. To anyone with knowledge of such affairs, this statement showed that the story could not be wholly veracious; for, though Messrs. Christie, as auctioneers, have been selling works of art for two centuries, they have never bought them or made offers of the kind described. We are sorry to have caused Messrs. Christie annoyance by this misleading mention of their name.

FEEDING CONVALESCENT PATIENTS
NUTRITIONAL NEEDS AND PRESENT COST*A. P. MEIKLEJOHN
D.M. Oxf'd, M.R.C.P.

LECTURER IN NUTRITION, DEPARTMENT OF MEDICINE, UNIVERSITY OF EDINBURGH; CONVENER, CATERING COMMITTEE, ASTLEY AINSLIE, EDENHALL, AND ASSOCIATED HOSPITALS BOARD OF MANAGEMENT

THE National Health Service Act for Scotland, 1947, enjoins hospital boards to provide "general services" for the hospitals in their charge. As yet there has been no precise definition of what these services should be. So far as I know, the first attempt at any such definition was made in a recent editorial in THE LANCET (March 20, 1954) which said: "the responsibility of hospital managements is to provide an efficient hospital, to keep it warm, clean, and wholesome, to furnish it for the adequate reception of patients, to supply it with the necessary food and medicine, and to employ a competent staff." This seems a good definition which might well provide the basis for future legal interpretations of the Act. In that event we would have to consider carefully what is meant by "necessary food." In fact we might have to consider it very carefully indeed. Now that any dissatisfied patient can ask for free legal aid, it is quite possible that before very long a hospital board might find itself sued for failing to provide "necessary food." The expert evidence in such a case would be interesting and probably so contradictory and confusing as to embarrass even the lawyers.

I want to attempt some definition of what should be meant by "necessary food" for convalescent patients, not out of any special desire to help the lawyers in their task—still less to provide material for office-desk directives—but because I believe that all of us concerned with the care of convalescent patients want to see them properly fed and are now anxious about how this can be done on our present budgets.

"NECESSARY FOOD" FOR CONVALESCENCE

It is surprising that no recent textbook of medicine, surgery, or therapeutics seems to pay any special attention to the general nutritional needs of convalescent patients, though they sometimes give advice about feeding during recovery from certain specific diseases. Some of this advice dates from an age when medicine was more elegant, though perhaps less efficient than it is today—e.g., the importance of avoiding overcooked meats, or game that has been allowed to get "high." A new British textbook of medicine edited by Garland and Phillips (1953) provides an admirable essay by Dr. T. F. Main on the special problems of convalescence and rehabilitation, particularly the psychological problems; it is an essay well worth study. And yet, surprisingly, the book makes no mention of nutritional needs in convalescence.

The provision of food for convalescent patients presents quite a different problem from feeding patients in the wards of a general hospital. In a general hospital there are always some patients who are too sick to take more than a light diet. The other patients benefit accordingly; for the catering officer, with a fixed allocation per bed of foods such as meat and butter, has usually a comfortable surplus to distribute. Convalescent patients, on the other hand, whether at home or in homes or hospitals, should be eating at least a full well-balanced normal diet. I say "at least" on purpose, because

there are several categories of convalescent patients who actually need more food than a normal healthy person.

SPECIAL NUTRITIONAL NEEDS IN CONVALESCENCE

It is no fault of the general hospitals that many of the patients they discharge to convalescent homes are actually in a state of subnutrition or malnutrition. In fact it is the correction of these inevitable nutritional deficiencies that is an essential part of what we mean by convalescence. These deficiencies are inevitable because they are the unpreventable aftermath of acute illness, operation, or injury. Here are some examples.

Calorie-deficiency (Subnutrition) Following Fevers

Loss of appetite is a common complaint in many acute febrile diseases. In the old days the doctor used to aid the process by denying his feverish patients all food, except perhaps an occasional cup of meat extract (devoid of calories) and a sliver of desiccated toast. The patient with a long-continued fever, such as typhoid, might recover from the infection only to die in the end of starvation. The first opponent of this mistaken regimen was the great Irish physician Graves, who asked that his tombstone should be inscribed with this epitaph: "He fed fevers." But for many years he had few followers. Today we try to coax the feverish patient to take as much food—as many calories—as he will accept by feeding him fluids and semi-solids of high energy value; not meat extract and "ice-creams" made of seaweed, but sustaining soups in which a whole meal is concentrated and made tasty, and puddings containing plenty of milk or concentrated milk-protein.

The advent of the antibiotics has undoubtedly greatly reduced the extent of subnutrition and starvation resulting from long febrile illnesses, because they have curtailed the number of days on which the patient is unable to eat. Even so, I suspect that there are still many patients recovering from fevers who have a great deal of nutritional leeway to make up. A familiar example is the child who has ceased to grow during an attack of whooping-cough, through losing calories by recurrent vomiting.

Malnutrition (Deficiency of Specific Nutrients) Resulting from Injury

Loss of nitrogen.—It is now generally recognised by surgeons that the common process of putting a patient to bed, giving him a general anaesthetic, and making a simple skin incision—no more than that—is enough to put him into "negative nitrogen balance." In other words his tissues begin to break down, liberating protein which is katabolised. The nitrogen liberated by this katabolism is excreted, so that more nitrogen appears in the urine than is taken in the food and a state of negative balance ensues. If, in addition, there is serious injury the negative balance will be correspondingly severe. Many surgeons have attempted to check this biological reaction to injury by giving heroic quantities of protein immediately, either by mouth in the form of concentrated milk-protein, or by intravenous infusion of protein hydrolysate. But the general opinion now seems to be that the effort is doomed to failure because it is impossible to arrest, at the time, this reaction involving the destruction of protoplasm. It is only during the stage of recovery—during convalescence—that the lost protoplasm can be replaced.

Loss of ascorbic acid (vitamin C).—Recent work has drawn attention to the relatively enormous amounts of ascorbic acid that may vanish from the body immediately after an injury, such as a fracture or burn. The body, when fully saturated with the vitamin (which few British people are) may contain 6 g. of the vitamin; as much as 4 g. may disappear overnight after an accident. It seems likely that the corticotrophin discharged from the anterior pituitary gland in such

* Lecture delivered on April 24, 1954, to a conference on Convalescent Homes arranged in London by King Edward's Hospital Fund.

circumstances, is responsible for this rapid disappearance of ascorbic acid; the liberation of this hormone from the anterior pituitary is known to be one important aspect of bodily reactions to damage. This loss of ascorbic acid must be made good during the period of recovery, and the diet must supply it because man, like the guinea-pig but unlike the rat, cannot make it for himself.

Loss of calcium.—A remarkable experiment carried out in America recently showed that when a normal man is put to bed immobilised in a plaster cast from chest to toes, his body goes into "negative calcium balance"—i.e., he loses more calcium in his excreta than he receives in his diet. The fact is that when for any reason any part of the skeleton is immobilised it loses calcium salts, becomes demineralised, and is thus weakened. The strength of the bones is maintained only by constant use. We know too well how elderly bedridden patients may by immobilisation lose so much calcium from their bones that, when they do get up, they break a hip as soon as they put any weight on it. The occupational therapist and physiotherapist, by providing active movements for bedridden patients, not only keep the muscles from atrophy but help to maintain the strength of the bones.

Dietary Sources of Calcium, Ascorbic Acid, and Nitrogen

By far the most valuable dietary source of calcium is milk, and the milk-protein contained in cheese. Ascorbic acid is provided by fresh fruit and vegetables, nitrogen by foods of animal origin—meat, fish, eggs, milk, cheese.

Of course all these foods are regularly provided in convalescent diets; but are they always provided in adequate amounts? Before attempting to answer that question, it is worth considering first what constitutes an adequate diet for a normal adult.

Definition of an Adequate Diet for a Normal Adult

It is impossible to predict from published tables of nutritional "requirements" just how much of each class of nutrient a patient needs; needs vary very widely and unaccountably from one individual to another. But it is useful nevertheless to have certain standards—"recommended allowances"—against which to judge the adequacy of diets. Such standards have been provided by the British Medical Association's Committee on Nutrition (1950). A normal adult should be able to maintain a satisfactory state of nutrition on the following approximate daily (intake) allowances:

Calories: 2000 to 4000 according to age, sex, and activity.
 Protein: At least 70 g.
 Calcium: 1 g.
 Iron: 12 mg.
 Vitamin A: 2500 I.U.
 Thiamine: 5 mg.
 Ascorbic acid: 30 mg.

What do these amounts mean in terms of actual foodstuffs? This may be learnt from a study of the reports of the National Food Survey carried out by the Ministry of Food during the 1939-45 war and after. This survey shows that the average diet of urban households has been, in recent years, sufficient to meet the B.M.A. recommended allowances. The average daily consumption of different foodstuffs¹ therefore provides a useful guide to the quantities of different foods, available on the market, necessary to provide an adequate diet for a British household. This publication also provides a valuable index of the rising cost of food.

THE COST OF FOOD

Cost of an Adequate Household Diet

Twenty years ago the British urban population was spending on average about 9s. per head per week on food. Times and costs have changed since then! We know that before the war the diets of many urban

families were seriously deficient in several respects. With the introduction of rationing during the war the average level of nutrition actually improved, while the price of food was kept low by subsidies.

For various technical reasons the figures given by the National Food Survey for the cost of an average urban diet are not strictly comparable from year to year. However, I do not think that the scientific advisers of the Ministry of Food will quarrel with me seriously when I give the following personal estimate of the changing cost of a household diet adequate to meet the B.M.A. standards, making due allowance for the relative inefficiency of the housewife in her choice of the best foods to buy:

Estimated Cost of an Adequate Household Diet (per head weekly)

1942-43	11/-
1946-47	11/6
1950	16/6
1951	19/6
1953	24/-

These figures are obviously only approximate, but I think it true to say that the over-all price of food has more than doubled in the last seven years and that an average urban family would not now be able to purchase an adequate diet for much less than 25s. per head per week. Fortunately many families have enjoyed a parallel increase in wages (earned from the rising prices); but it is hard on old people with fixed incomes, and also hard on hospitals. In budgeting for hospital catering we must dismiss from our minds all former ideas about what this should cost, and accept the fact that, as regards food at least, we are living in times of inflation.

Obviously it would be foolish, without full knowledge of the economic facts, to question the wisdom of lifting the subsidised lid on food prices. There are already signs that the price of some foods is falling. But meantime it seems reasonable to express the hope that the Ministry of Health understands what the Ministry of Food is doing.

Hospital Costs and Household Costs Compared

It may be argued that a hospital should be able to provide food at much less cost than the ordinary household, by reason of wholesale purchases. This is certainly true to some extent, but against this must be reckoned certain factors that may add to the catering costs of hospitals.

Age of the patients.—The figures I have given for the cost of domestic feeding are in terms of a household budget divided by the number of members in the family, including small children whose nutritional needs are obviously much less than those of an adult. A hospital providing mainly for adults would have to purchase more food per head than the average household.

Special nutritional needs in convalescence.—I have already given some reasons why convalescent patients should have ample supplies of milk, meat, and fresh fruit and vegetables as a necessary part of their treatment.

Milk

The average household purchases about 5 pints of milk per head per week. In my opinion a convalescent hospital should provide at least 7 pints at an additional cost of about 1s. per head per week.

Meat

Meat seems to be rationed more by price than anything else now, and I suspect that many families have had to alter their eating habits and accept stews made from the cheaper cuts in place of the traditional roast. It is clearly important that convalescent hospitals should not imitate the public in this respect, and attempt to save money by debasing the quality of the food they serve. A diet, to be therapeutically useful, must be appetising. The quantity of meat purchased may look very impressive on paper, but it is useless if it is inedible.

Fruit and Vegetables

Likewise I suspect that some households now find the price of many fruits and vegetables prohibitive, particularly

1. Domestic Food Consumption and Expenditure, 1951. H.M. Stationery Office, 1953.

in the first months of the year. The ascorbic acid which they provide is the one vitamin that is commonly consumed in insufficient amounts in Britain.

A great deal of this vitamin is destroyed in the appalling traditional ways of cooking potatoes and other vegetables. The average domestic diet contains 50–70 mg. per head per day (according to season) before it is cooked, but a large part of this is destroyed in the cooking. By American standards we are certainly all of us deficient in this vitamin. Although I doubt whether keeping the body saturated with it is really necessary for health, as the Americans think, I believe that many British people—especially in the spring—have inadequate bodily reserves of ascorbic acid. A survey of blood-ascorbic-acid levels among hospital patients would almost certainly show an important proportion with little or no measurable amount of the vitamin at this season of the year.

The average domestic household spends about 1s. per head per week on fresh fruit. I would think that a convalescent hospital ought to be spending at least twice this amount, if its patients are to recover quickly from the loss of ascorbic acid sustained as a result of surgery or injury.

VALUE OF A GARDEN

At the Astley Ainslie (Convalescent) Hospital in Edinburgh we have the inestimable advantage of well-kept gardens. These provide a pleasant environment in which patients may rest, relax, and recover. In my opinion the cost of maintaining them is money that is far more usefully spent towards the benefit of patients than the large sums sometimes expended on drugs of dubious value in hospitals less fortunate.

But more important than the psychotherapeutic amenity that gardens provide are the fruit and vegetables they produce. The Astley Ainslie Hospital has 8½ acres of land devoted to market gardening, which grows a substantial part of the requirements for fruit and vegetables for a hospital of 240 beds. Fruit and vegetables sold in the markets of large cities have often been "processed" in various ways to maintain their appearance, though not necessarily their nutritive value. The ascorbic acid content of vegetable foods deteriorates rapidly with keeping. To be able to give convalescent patients fruit and vegetables fresh from the garden, without spoilage, is a most important means of providing the ascorbic acid they need, and incidentally it is more enjoyable for them than vitamin pills.

There can be no dispute that a garden is a priceless asset to a hospital, and any attempt to reduce its productivity in the name of economy should be resisted on medical grounds.

VITAMIN PILLS

It is fashionable at the present time to prescribe multi-vitamin pills of various kinds to convalescent patients. The doctors who prescribe them have probably very little notion of what is in them. They may notice that they contain pyridoxine and pantothenic acid and think that this is all very scientific and good. But there is no evidence that the human body needs these particular vitamins in its food; in fact there are reasons for believing that pyridoxine may be injurious, if the diet is deficient in another component of the B-complex—thiamine.

Vitamin pills are no substitute for food, and personally I know of very few medical uses for them. Admittedly they are valuable in the immediate treatment of beriberi, pellagra, and scurvy, but these diseases are almost extinct in Britain. My personal view is that no convalescent patient should require synthetic vitamin pills if he is provided with proper food.

Before the discovery of the vitamins, every patient in hospital had a bottle of medicine; often it was mostly infusion of gentian or some other bitter tonic intended to stimulate the patients' appetites for the nauseous meal that they were about to receive. Fortunately the members of the British Dietetic Association, with well-trained cooks and catering officers, have so improved the

standard of hospital feeding that tonics are no longer necessary.

PRESENT COST OF A CONVALESCENT DIET

But to return to the main theme; what is the minimum cost of an adequate convalescent diet? I think that today it would be difficult adequately to feed convalescent patients on much under 25s. a week, at least at the food prices current in Edinburgh.

At the Astley Ainslie Hospital, during the first two months of this year, we were actually spending 23s. 9d. a week on food; but then we have the advantage of our own market garden. This compares with the average figure of 12s. 6d. a week that we were spending during the twelve months April–March, 1946–47.

How do we know that the diet we are providing is adequate? I have obtained the records of kitchen allocations of food at the Astley Ainslie Hospital for a sample week in March, 1954, and had them calculated in terms of calories and nutrients. I am glad to say that they meet the B.M.A. standards, even allowing for inevitable cooking losses. But there is not a great deal to spare, keeping in mind the special nutritional needs of convalescent patients.

I would be the last to suggest that we should have periodic visitations from official dietetic auditors to top up the calories in the kitchen, along with the petty cash; but I do suggest that every convalescent home or hospital should review for itself periodically the standard of its feeding, preferably with the help of a trained dietitian, to make certain that minor economies have not been allowed insidiously to undermine the standard.

COMMENT

It is ironical that at this time, when civilian rationing is at last coming to an end, hospitals are finding it necessary to impose their own system of rationing food in order to keep down expenditure. I suggest that they ought to think very carefully before they do so. I have heard of one hospital where it was recently proposed that they should economise on their milk bill, while at the same time the medical staff was freely prescribing injections of expensive antibiotics which were sometimes given for days after the patient really needed them "just to make sure," or because no-one had remembered to cross the order off the treatment sheet. If economies must be made, I suggest that we scrutinise first the drug bill—and especially the bill for synthetic vitamins.

Good food is an essential part of proper convalescent treatment. It is obviously false economy to employ an expensive staff to look after convalescent patients whose recovery is postponed and delayed because they are not getting proper food.

AN AMERICAN IN BRITAIN

Dr. J. H. Cort, a citizen of the U.S.A. who is lecturer in physiology in the University of Birmingham, was ordered last week to leave Britain by June 30.

Dr. Cort issued the following statement:

I came to this country for the second time in June, 1951, directly after completion of medical school at Yale University. My research interests at Yale had been in electrolyte metabolism and renal physiology, and I was awarded a research fellowship for two years with R. A. McCance at Cambridge. For two years, while a medical student, I had been a member of the American Communist Party. My sole political activity during that period was as a member of the Association of Internes and Medical Students, advocating health insurance and a national health service in the United States. This political activity ceased after medical school, and I have now no political affiliations or activities. I left the U.S. lawfully, with a valid passport, in May, 1951. In November, 1951, the American Embassy in London demanded the return of my passport and my immediate return to the United States. I

asked the reason for this request, but was told only that the State Department had issued the request and that no reason could be given. I was very loth to comply since I had only been in my fellowship for three months, and I had also registered as a research student at Cambridge. My legal adviser informed me that there was no legal compulsion in the request, and since I had very little reason to expect that scientific employment would be available for me under present conditions in the U.S. I did not comply with the request. In June, 1952, my passport expired. I applied for renewal of permit to stay, and the Home Office granted this with full knowledge of my status.

In the course of the next year, the Congressional Committee on Un-American Activities began investigating "subversive activity" in American universities, and, in the course of their hearings at Yale and in Boston, many of my old acquaintances were asked if they knew me, I being identified as a member of "a secret Communist cell" at Yale. These identifications were publicly printed, appearing in some detail in at least a dozen American newspapers. All of my friends who refused legally to testify were dismissed from university posts except one at Harvard. There, the university refused to dismiss him, but the Massachusetts authorities have indicted him for violating his oath to the university and the State, even though the university is not the complainant, and he is awaiting trial at present. Later, the U.S. Army began a loyalty oath programme, under which all candidates for call-up and commission were required to list all political organisations with which they had been connected. If membership of any organisation on the official "subversive list" was admitted, past or present, or if the candidate legally refused to fill in the form, he was called up as a private, regardless of medical qualifications or experience. Two of my friends so inducted have subsequently undergone court-martial for subversive activity supposedly undertaken before military service, and one has been dishonourably discharged. Last month, the U.S. Army's policy was changed, so that former and present Communists and "subversives" are not allowed into the armed Services at all.

Because of these considerations I considered that I would find it impossible to continue my scientific and medical career in the United States, and I applied in December, 1952, for a lectureship in physiology at the University of Birmingham, a permanent position. This post was awarded to me in February, 1953. In March, 1953, I received an order to appear for examination and induction into the U.S. Army either in America or Germany. I again took legal advice, and was informed that under British and international law I could only receive notice of intention, but that no legally binding notice could be served on me by a foreign government in the United Kingdom, and that my only legal obligation was to report for service upon returning to the jurisdiction of the demanding authority. I therefore did not report as ordered. The order was repeated several times, despite the fact that my parents informed the U.S. authorities of my legal position. After taking up my duties in Birmingham, the Home Office again renewed my permit to stay.

In December, 1953, I was called to the criminal investigation department of the Birmingham Police to have a message from the U.S. Embassy read out to me and to have a reply taken. This message stated that:

- (1) I was a delinquent, and had violated American Law.
- (2) I had left the U.S. without permission.
- (3) I had refused to obey legally binding call-up orders.
- (4) I had left the U.S. for the purpose of evading National Service.

The wording of (4) was important since the message went on to say that, under the McCarran Law, this last charge would be used to remove my U.S. citizenship. I was unable to get any legal advice here that professed competence in U.S. law, so that I was forced to give an official answer that merely stated that I denied the charges, and that I refused to give a detailed statement to the U.S. authorities through the agency of the criminal investigation department of the British Police, but that should the Home Office require any information I should be happy to furnish it. For the purpose of this statement, may I state in answer to the charges:

- (2) I left the U.S. with a legally valid passport. I registered with the army authorities before I was legally required to do so in order that I might be able to travel in time to take my position at Cambridge. I asked the army authorities and the University (Yale) consultant on military service whether there were any formalities in

leaving for my post, and I was told that there were none, and that I should leave.

- (3) These orders were not legally binding.
- (4) In addition to the facts stated in answer (2), I would only point out that I left the U.S. over two years before I received any induction notices, and I never had advance knowledge of these notices.

I was then notified by the Home Office that they were consulting with the U.S. Embassy on this matter. The Home Office did not request any information from me. In March, 1954, the Home Office informed me that if my citizenship were revoked they would cancel my permit to stay, and that they would not renew it under this circumstance in June, 1954.

The Home Office was approached by the Vice-Chancellor of the University of Birmingham, by Professor A. V. Hill, F.R.S., and by A. Wedgwood Benn, M.P., who supported my request to be allowed to remain in the U.K. Mr. Benn stated that he considered that I should be granted political asylum.

The Home Secretary replied that:

- (1) It would be a dangerous precedent to allow me to remain here.
 - (2) Political asylum is only considered when life is endangered.
 - (3) I would not be allowed to remain here after June 30.
- The penalties that I face, apart from lack of employment, if forced to return to the U.S., are loss of citizenship and 5-10 years in prison.

My own wish is to settle down quietly in the U.K., and to continue my scientific work. I firmly believe that my legal and moral position is quite justified and clear.

Up till last Tuesday neither the Home Office nor the United States Embassy had commented in detail on Dr. Cort's case; but the Embassy described the statutory obligation of U.S. nationals liable to National Service to obtain a permit from their selective service board before leaving the U.S.A., and, if they remained long abroad, to report for medical examination or induction when so required. Dr. Cort declared (*Manchester Guardian*, June 15) that he was cleared by his local draft board when he left the U.S.A. in May, 1951; it was only after his name had been mentioned in investigating committee hearings that he had refused to return for enlistment.

BIRTHDAY HONOURS

The list of honours published on June 10 contains the names of the following members of the medical profession:

Baronet

Sir RUSSELL BRAIN, D.M. Oxfd, LL.D.
President of the Royal College of Physicians of London; physician to the London Hospital.

C.H.

WILLIAM SOMERSET MAUGHAM, D.LITT. Oxfd, M.R.C.S.
Author and dramatist.

Knights Bachelor

RUSSELL CLAUDE BROCK, M.S. Lond., F.R.C.S.
Surgeon, Guy's Hospital and Brompton Hospital, London.
ALEXANDER PATERSON MURPHY, M.C., M.D. Sydney, F.R.C.P.
President of the Royal Australasian College of Physicians.
HERBERT HENRY SCHLINK, M.B. Sydney, F.R.A.C.S., F.R.C.O.G.
Consulting gynaecological surgeon, Royal Prince Alfred Hospital, Sydney.

C.B. (Military)

Major-General WILLIAM ALEXANDER DUNCAN DRUMMOND,
C.B.E., F.R.C.S.
Major-General RICHARD MURPHY, C.B.E., M.B. Dubl., Q.H.S.

C.M.G.

ROBERT SAMUEL FLEMING HENNESSEY, M.D. Dubl., F.R.C.P.I.
Director of medical services, Uganda.
ANDREW TOPPING, T.D., M.A., M.D. Aberd., F.R.C.P.
Dean, London School of Hygiene and Tropical Medicine.

C.B.E. (Civil)

- CHETWYND JOHN PERSHALL GROSVENOR, M.A., M.B. Camb.
Principal medical officer, Ministry of Pensions and National Insurance.
- JOHN LEWIS ANDERTON GROUT, M.C., F.R.C.S.E., F.F.R.
Senior consultant radiologist, Sheffield United Hospitals.
- MAXWELL SHAW JONES, M.D. Edin., M.R.C.P.E.
Director, social rehabilitation unit, Belmont Hospital, Sutton, Surrey.
- NEVILLE LANGDON LLOYD, M.B. Lond., M.R.C.P.
Chief medical officer, Ministry of Supply.
- PHILIP PATRICK LYNCH, M.D. N.Z., F.R.A.C.P.
Pathologist, Wellington, New Zealand.
- ARTHUR JOHN METCALFE, M.B. Sydney.
Director-general of health, Commonwealth of Australia.

HUDDERSFIELD LECTURER IN SPECIAL PATHOLOGY

A PREVIOUS report (Marmion et al. 1953) described some aspects of the epidemiology of human cases of Q fever in Great Britain but drew no final conclusions about the animal sources of infection in this country.

Attention was drawn to the larger number of clinical cases of Q fever which had been detected in Kent compared with several counties in East Anglia (see table 1). Tests of sera from healthy blood-donors living in these two areas also suggested an uneven distribution

TABLE 1—Q FEVER AND STOCKING IN DIFFERENT COUNTIES

County	Human population per sq. mile		Animals per 100 acres of crops and grass			% of herds of cows infected†	% of blood-donors serologically infected†	Clinical cases of Q fever 1946-51

Norfolk, Suffolk, Cambridgeshire, Isle of Ely, and Huntingdonshire	266	205	15.4	6.1	12.6	0.24	0.8	0

* Population per square mile, excluding towns with more than 50,000 inhabitants.

† Herd-milk samples containing *R. burneti* demonstrable by guinea-pig inoculation.

‡ Percentage of blood-donors' sera which contained complement-fixing antibody at a titre of 1/10 or above (Henzenling antigen 1950-51 survey).

of infection, because complement-fixing antibodies for *Rickettsia burneti* were found in 3.29% of Kentish donors compared with 0.8% of those in the eastern counties. Although the factors causing this uneven prevalence of human infection are not yet clear, it is felt that differences in the numbers and species of domestic animals available as sources of human infection in the two areas might be partly responsible.

Table 1 shows that the density of stocking with cattle in the two areas is about the same: 15-19 cows per 100 acres of crops and grass. Infection with *R. burneti* appears to be commoner in Kentish cattle, judged by tests of herd-milk samples: 8.2% positive in Kent against 0.24% in the eastern counties. This difference may contribute to the relative prevalences of Q fever in man in the two areas. However, apart from infection in the cattle, the areas differ strikingly in numbers of sheep (table 1).

* This work was done from the Department of Pathology, Tennis Court Road, Cambridge, as part of an investigation of Q fever in Great Britain supported jointly by the Medical Research Council and the University of Cambridge.

† Seconded for the purpose of this investigation.

That infection of sheep with *R. burneti* takes place in Nature was shown by Caminopetros (1948), who isolated the organism from the milk of sheep in Greece. Infected sheep have also been found in North California (Lennette et al. 1949), in Italy (Baldelli 1950, Caporale 1950), and in Portugal (Fonseca et al. 1951). The results of epidemiological investigations in all these places suggest that sheep can be responsible for human infection.

If in Kent sheep were infected, as well as cattle, this would be an additional explanation for the prevalence of the disease in that county. For this reason Kentish sheep were investigated, and in a certain area of Kent with particularly large numbers of sheep infection in both human beings and sheep has been found. This finding introduces a new element into the epidemiology of Q fever in Great Britain.

Methods

CHOICE OF AREA FOR INVESTIGATION

In many parts of Kent cattle and sheep are found together in the same areas in numbers which complicate identification of one or other animal as a source of human infection. Because of this it was decided to search for human cases of Q fever and infected sheep in Romney Marsh. This is well known as a traditional place for the breeding and fattening of sheep, and its pastures carry a very large number, particularly during the summer. Romney Marsh is a small area about 31,000 acres (48.4 sq. miles). The number of sheep is large (about 287 per 100 acres of crops and grass) compared with the number of cattle (10 per 100 acres of crops and grass). The human population of the Marsh is sparse (9247) and mostly found in the towns of Lydd, New Romney, Greatstone, Littlestone, and Dymchurch. Except in 1 person who lived at Lydd, no cases of Q fever had been recognised in the area during the earlier investigation from 1949 to 1951.

DETECTION OF Q FEVER IN MAN

Two methods were used. First, a list of persons notified to the medical officer of health as having had "pneumonia," "primary pneumonia," or "influenzal pneumonia" in 1949-53 was obtained through the kindness of Dr. J. Marshall, M.O.H. for the area. Secondly, with the help of the medical practitioners in the area, a number of persons who had had a febrile illness in 1949-53 but had not been notified as having "pneumonia," were collected. These two groups of patients, with the exception of children aged less than 10 years, were then visited, their co-operation was sought, and a sample of their blood was tested for complement-fixing antibody to *R. burneti* (Nine Mile strain antigen). Those persons who both had had a clinically suggestive illness and had a complement-fixing antibody titre of 1/40 or more were considered to have been cases of Q fever and were investigated epidemiologically. Serological tests of healthy volunteers among inhabitants of the Marsh were also made to provide both a standard against which the serological results of the patients could be interpreted and an indication of the degree of exposure of Marsh residents to *R. burneti*.

INVESTIGATION OF SHEEP IN KENT AND ROMNEY MARSH

At the beginning of the investigation, when it was still uncertain whether sheep in Kent were infected at all, specimens of blood were collected as animals were slaughtered at various Ministry of Food abattoirs in Kent. These sheep had been kept in various parts of Kent but were of differing age, sex, and breeding history. After the detection of human cases of Q fever in Romney Marsh and when the epidemiological investigation implicated sheep, particular flocks of these animals were examined. 5-10 ml. of blood was collected from the jugular vein of the ewes. The sera from these blood samples were tested for complement-fixing antibodies to *R. burneti*. The complement-fixation test using the Nine Mile strain of *R. burneti* as antigen was applied at first, and later many sera were retested with Henzlering strain antigen because this was found to be more satisfactory with sera from Kentish sheep. A suspension of murine typhus rickettsiae was used as a control antigen in all the tests, and only those sera which reacted with *R. burneti* and did not react with this antigen were considered to contain specific antibody.

Further investigations are being made in Romney Marsh to find out more about clinical and subclinical infections in man and their relation to infection among sheep and cattle. Corresponding investigations, as a control, are also being made in a geographically similar area of the Fenlands near Cambridge, which has a human and cattle population resembling that of Romney Marsh but differs considerably from it in its numbers of sheep.

Results

Q FEVER IN MAN IN ROMNEY MARSH

From February, 1949, to August, 1953, 90 persons were notified as having "pneumonia." This represents a "pneumonia-rate" of about 2.4 per 1000 of the

TABLE II—FREQUENCY DISTRIBUTION OF TITRES OF COMPLEMENT-FIXING ANTIBODIES TO *R. burneti* IN SERA OF SICK AND HEALTHY PERSONS IN ROMNEY MARSH

Group investigated	Number of persons with complement-fixing antibodies to <i>R. burneti</i> at titres of							Total
	< 5	5	10	20	40	80	160	
"Pneumonia" or febrile illness	35	7	5	5	1	3	6	62
Controls (see text) ..	76	8	14	1	1	0	0	100

population per year. Of these 90 persons 27 were children aged less than 10 years, who have not yet been investigated. 38 of the remaining 63 patients notified as having "pneumonia," &c., and 24 persons who had had unexplained febrile illness according to medical practitioners' records, making a total of 62, have been tested serologically. Of this group 10 (16%) have provided complement-fixing antibodies to *R. burneti* at a titre of 1/40 or greater. Sera from 17 persons in the group gave lower complement-fixing antibody titres from 1/5 to 1/20, and 35 were negative at < 1/5 (table II).

It is important to know how often complement-fixing antibody at a titre of 1/40 or above would be found in healthy persons living in the Marsh, because there might be merely a chance association between the occurrence of illness and the presence of antibody in any particular person with pneumonia or fever. Examination of sera from 100 healthy controls showed that, though complement-fixing antibody is commonly found in Marsh inhabitants (16% of sera reacted at a titre of 1/10 or greater), levels of 1/40 or greater were more often found in the sera of "pneumonia" and "fever" patients (16%) than in those of the controls (1%) (table II) ($\chi^2 = 11.5$; $p = < 0.001$). Our supposition, therefore, that persons with antibody at titres of 1/40 or greater who had had clinically suggestive illness had probably had Q fever is not unreasonable. Accordingly, for

Relationship between antibody levels to *R. burneti* in patients with "pneumonia" or with pyrexia of obscure origin and time of year of onset of illness. Times of lambing and shearing are also shown.

convenience, these persons are referred to below as patients who had had Q fever.

The accompanying figure shows the titres of antibody in the sera of the "pneumonia" and "fever" patients in relation to the month of the year when their illness began. It can be seen that the 10 patients with complement-fixing antibody at titres of 1/40 or over—the patients who had had Q fever—began their illness during the period from the second half of March to the first half of June. This is the period of the year when there is much activity with the sheep on the farms, including lambing (March and April) and shearing (June). In addition to these 10 sporadic cases, an outbreak of 10 cases of Q fever was identified in retrospect among the cast of a religious play held at a small village in the central part of the Marsh. This happened during the lambing period (see figure).

Q FEVER IN KENTISH SHEEP AND ITS RELATION TO HUMAN INFECTION

Serological Infection-rates in Kentish Sheep

906 sera from sheep killed in Kent slaughter-houses were examined for complement-fixing antibodies, the Nine Mile strain of *R. burneti* being used as antigen. 15 (1.6%) had antibody titres of 1/10 or greater.

Epidemiological Investigation of Human Q Fever and Sheep in Romney Marsh

Five flocks of sheep associated with three groups of Q-fever patients were examined.

Flock 1 was on a large farm where two agricultural workers had had Q fever in March and April, 1952.

Flocks 2, 3, and 4 were pastured on various sides of the village where the outbreak of Q fever had occurred in April, 1949, and there was subsequently another case, Mr. A, in 1952. Flock 3 is of special interest because it had lambed in a field at the back of the row of houses where Mr. A lived.

Flock 5 is likewise of special interest, because it was associated with a patient who developed Q fever during the investigation—a fact which enabled a current, rather than retrospective, investigation of a flock to be made. For this reason the episode is described in more detail:

Mr. B, aged 26, who had not previously worked on the land, left the Royal Navy in September, 1952. In October, 1952, he was engaged as shepherd for flock 5. He was in good health until April 27, 1953, when he felt listless and alternately hot and cold. Next day he developed a severe headache and pains in the limbs, profuse sweating, and pyrexia (101°–102°F). He was ill for about a week in all. Tests of specimens of serum taken on the fourth and twentieth days of illness showed complement-fixing antibody titres of < 1/5 and 1/160 to *R. burneti*. A mild attack of Q fever was diagnosed.

The sheep in flock 5 are pastured on an isolated farm, where there are no cattle, goats, or pigs. Mr. B had not had contact with cattle, sheep, goats, or pigs on other farms at the time (April 4–14) when he probably acquired his infection. Lambing started in flock 5 on March 28 and was most frequent during the first week of April, about twenty days before the onset of Mr. B's illness. During the lambing period Mr. B was naturally much occupied with the delivery of the ewes and care of the lambs. Mr. B used in his household raw milk from a local dairy. Milk supplied by this dairy was tested and did not contain *R. burneti* demonstrable by guinea-pig inoculation. The herd of cattle from which it had come did not give serological evidence of infection with the organism.

From table III it can be seen that 7.7% of the sera from sheep in flock 5 had complement-fixing antibody at titres of 1/10 or above when tested with Henzerling-strain antigen. The facts that this flock was infected; that it had lambed at a time (about twenty days before the onset of illness) when Mr. B must have acquired his infection; that Mr. B was not exposed to other

* Flocks associated with a case or cases of human Q fever.

possible sources of infection, such as parturient cattle or goats, or infected milk from these animals, are all in accord with the view that he was infected from his sheep.

Similarly, serological evidence of infection was found in flocks 1 and 3 associated with the other cases of Q fever. In flock 3 the high figure of 33.7% positive was obtained. This figure was considerably higher than that observed among ewes in flocks 2 and 4, which were rather more distant from Mr. A's house (table III).

Discussion

The epidemiology of human Q fever due to infection from sheep has a suggestive pattern, of which one feature is the limited seasonal incidence of cases. Thus in North California human Q-fever is commonest from February to May (Clark et al. 1951), the months just after lambing and when sheep are being castrated, "docked," shorn, and generally much handled and moved. The epidemiological importance of parturition in sheep and the period immediately following it has been emphasised by several observers (Lennette 1950, Caporale 1950). *R. burneti* has been found in large numbers in the placenta (Welsh et al. 1951), birth fluids (Abinanti et al. 1953), and faeces (Winn et al. 1953) of parturient sheep. It is also excreted in the milk (Caminopetros 1948, Lennette et al. 1949) after parturition, but this is probably of less epidemiological significance than parturition as such, except perhaps in countries where sheep's milk is widely drunk or made into cheese.

This sudden and intense excretion of rickettsiae at parturition, together with the increased farming activity and, perhaps, meteorological conditions favouring dissemination in dust, lead to a sharp seasonal prevalence of human Q fever.

Some features of the pattern have been found in the Romney Marsh. Q fever appears to be fairly common in the inhabitants of the area. About 16% of a group of patients who had had pneumonia or obscure fever had serological evidence of infection with *R. burneti*, suggesting that they had had Q fever. Subclinical infection of the Marsh inhabitants also appears to be common, because a similar percentage (16%) of healthy persons tested had antibody but at lower titres than the patients who had probably had Q fever. Serological examination of sheep in the Marsh shows them to be infected, and there is suggestive evidence that this infection is responsible for that of human beings in the area. Thus, infected sheep have been found in the vicinity of human cases of Q fever—e.g., in the incident of Mr. B and his flock—and the onsets of illness in the patients with Q fever are closely grouped in time and related to lambing and shearing (see figure).

The possibility that some other domestic animal is the primary source of Q fever in the Marsh is being further explored. There are only a few pigs and an occasional goat in the area; so cattle seem to offer the only likely alternative to sheep as a source of infection. It is improbable, however, that cattle are commonly the source of the human infections. If the birth of young,

with its attendant dissemination of rickettsias, is directly or indirectly the occasion of human infection, the number of births in either cattle or sheep during the relevant period will determine the importance of the species as a source of human infection, provided that infection-rates in the two species are not grossly disproportionate, and that parturition takes place in similar environments. In the Marsh from March to June, in which season the human cases of Q fever occurred, about 20,000 lambs and 300 calves are usually born. There is no evidence that cattle in the area are commonly infected; hence the sheep seem to be the more important on this numerical basis. In addition to this, from July to February about 400-500 calves were born, but no cases of Q fever were detected (see figure).

Lastly, dissemination of infection from cattle by their milk, which would give an effect out of proportion to their numbers, also would not completely explain the findings. Consumption of an infected milk-supply would account for the infection of only 3 of the 10 sporadic cases and is unlikely to have been the cause of the outbreak of 10 cases.

In the studies of sheep as a source of human Q fever in North California Lennette et al. (1949, 1951) have pointed out that a greater proportion of serologically positive sheep are usually found in flocks associated with cases of Q fever than in those coming to slaughter at abattoirs. It is indeed reasonable to expect such differences between flocks in which infection is active and, where as a consequence, there would be a greater probability of man being infected, compared with a sample of the sheep population at large.

In the present investigation serological infection-rates in sheep in flocks 1, 3, and 5 were from three to five times as high as in sheep at Kentish slaughter-houses. (All the sera were tested with the same—Nine Mile—antigen.)

However, the validity of such comparisons needs further assessment, for they must be influenced in addition, and to an unknown extent, by differences in the age, sex, breeding-experience, and time of testing of the two populations which are being compared.

The levels of complement-fixing antibody to *E. burneti* found in the sera of sheep we have tested were mostly low (table III), but the finding of some sera with antibody at titres of 1/40-1/80 in the absence of reaction with the control murine-typhus antigen is considered to be a demonstration of specific antibody and evidence of infection of the sheep with *E. burneti*.

The fact that sheep in Kent are both numerically common and infected may, as already stated, go some way to explaining the frequency of human clinical and subclinical infection in this county. Infection of man from sheep does not appear to provide the entire explanation, however, because at least 35% of our original series of sporadic cases of Q fever in Kent as a whole, in contrast to Romney Marsh, occurred at times of the year or in circumstances where infection from sheep was unlikely.

Summary

Tests of sheep in Kent have shown them to have serological evidence of infection with *E. burneti*.

Investigation of a small area of Kent heavily stocked with sheep has shown that clinical and subclinical Q fever is common in the community and that sheep give serological evidence of infection.

Some evidence is presented that infection of sheep is responsible for infection of man in this area.

We are indebted to general practitioners in the Romney Marsh area for information about and permission to visit their patients. Dr. P. M. Vicary and Dr. E. Leiser Lonbay gave much-appreciated help with bleeding of patients, and in addition Dr. Vicary undertook the bleeding of the healthy volunteers. Dr. J. Marshall, M.O.H. for the area, and his

staff have helped us with local information and advice. We are grateful to the Ministry of Food and the slaughter-house managers at Ashford, Canterbury, Hythe, Ramsgate, Rochester, Sandwich, Sittingbourne, and Woolwich for collecting specimens of blood from sheep. Mr. A. J. Beeson, the divisional veterinary officer, advised us on the investigation of animals in the field, and his staff, in particular Miss M. J. B. Wheatley, helped us to bleed the sheep and cattle. We received valuable information about agricultural statistics from Mr. R. Duncan and Mr. T. Kimmins of the Agricultural Executive Committee, Maidstone. Lastly, we are grateful to the various farmers in the Marsh who gave us unstinted help during the bleeding of their sheep, and to Miss F. M. Callaby, Miss Z. E. Page, and Mr. P. C. Collings who did the laboratory work.

General Practitioner and Health Visitor

Dr. J. F. Warin, medical officer of health for Oxford, in his annual report for 1953 remarks that lack of correspondence between the districts covered by individual general practitioners and health visitors had made it difficult to organise liaison between them. He met the general practitioners in groups, and thereafter each was allocated a health visitor who worked in his area. The object of this arrangement was to enable every practitioner to know personally a health visitor whom he could approach for help with any problem in his practice. It is too soon, says Dr. Warin, to comment on the result of this arrangement; but a closer understanding between family doctor and health visitor is already apparent.

Dr. Warin remarks on the excellent liaison between the staff responsible for the care of the mother in the lying-in period and the health visitor, who receives a written report on the mother's discharge from the care of hospital or midwife. One of the health visitors goes every week to the lying-in ward of each of the maternity departments, and wherever possible domiciliary midwife and health visitor meet in the mother's house. Health visitors also attend paediatric sessions at local hospitals.

Epidemiology of Poliomyelitis

In his annual report for 1952, Dr. J. Stevenson Logan, medical officer of health for Southend-on-Sea, describes a serious outbreak of poliomyelitis which began in June of that year and continued for twenty-seven weeks, involving 98 cases—41 paralytic and 57 non-paralytic. The lack of an admission unit at the infectious-diseases hospital makes it necessary for patients to be visited, before removal to hospital, either by the hospital superintendent or by a doctor from the public-health department. Thus general practitioners in the area have become accustomed to notifying suspected cases promptly; and the information about the poliomyelitis cases is unusually complete—with 1 exception the diagnosis of the non-paralytic cases rested on changes in the cerebrospinal fluid.

In investigations of the chains of contacts one striking feature was the frequency with which school-teachers were encountered; but there was no proof that the teachers' households were unusually prone to infection. The families of medical practitioners entirely escaped the disease.

In England Now

A Running Commentary by Peripatetic Correspondents

As a morbid anatomist, I have acquired a certain degree of occupational anosmia, but even my experienced hippocampus reacted to my fellow passenger. I took a sidelong glance; she was an old woman with the face of starvation, the bright and abstracted eye of lunacy, and a tangle of grey and filthy hair. She was surrounded, rather than clad, by a series of ancient garments, culminating in an incredibly patched coat, gaping at the shoulders, with many pins (non-safety) trying in vain to bring the edges of the rents together. On her knees was an old string-bag and some newspaper wrapped round a single shoe. Here at least, I thought, was unusual company, dilapidation of a Dickensian extravagance.

The portress on the platform screamed: "Mind the doors!" The doors closed. As the train moved off, my companion turned to me and observed, in the accent and intonation of a university drawing-room, "These station women have such raucous voices, haven't they?" Startled into incoherence, I could only mumble "Yes" and await further revelations. But the oracle had spoken, and finally. She mused contentedly over her pronouncement for a few minutes, then took out her false teeth, laid them carefully on her lap with the shoes and string bag, and went to sleep. I felt rather guilty when I had to waken her to let me get out at my destination, but she was very affable.

What a life-saving drug our snobbery can be—surely not a sin or a virtue, but a great gift from a kindly Heaven.

The art of reading in a bath, according to 'Q,' is rarely attained, but my great toe has now been trained to turn the hot and cold on and off. Reprints are excellent material; or, if I am already saturated with medical matters, an *Everyman* edition is well supported; and what better than *The Diary of Samuel Pepys*. But even he sets me thinking about medical matters when he writes of the plague. In those days all seemed to be attributed to it. On April 8, 1666 (Lord's Day):

"The Court full this morning of the news of Tom Cheffin's death, the King's closet-keeper. He was as well last night as ever, playing at tables in the house, and not very ill this morning at six o'clock, yet dead before seven; they think, of an imposthume in his breast. But it looks fearfully among people now-a-days, the plague, as we hear, encreasing every where again."

I fell to wondering whether a modern coroner might not bring in a different verdict, and so to bed.

In my own neighbourhood my people still refer to me as "the doctor," and, despite increasing years, in my own mind I am still active, alert, and quite a young man. But the other day on holiday in a remote village where I was a complete stranger, and not the well-accepted figure lately retired from a busy practice, I popped into the local for a glass of beer. Apart from the landlord, behind the bar, there was only another man in the room—an ancient, dilapidated fellow with unshaven red cheeks and watery eyes. A real old chronic, I thought, and nothing much to talk to.

"Good morning," I said, embracing them both in my cheery salutation.

"Good morning, Sir," said the landlord.

"Good morning, Dad," said the ancient.

Dad! Dad! Dad! The word had a sinister ring about it, coming from such a source. "Good gracious," I thought "am I as old-looking as all that?" I felt hurt; the beer didn't taste at all good; there was something undoubtedly wrong—even with having a holiday. Out in the sunshine, however, I reflected how often I had myself told people to remember they were getting older and that they should "ease up." Had I perhaps unwittingly hurt them, just as the old man in the pub had hurt me?

"Dad," he had said. Oh, yes, I would remember. I would remember that, just as ageing is usually a

gradual, slow-moving, gentle process, so giving advice about it should be tempered with great kindness, patient understanding, and quiet dignity.

There is no rest-house in the little village where I spent Easter, and I slept under a tree not far from the chief's compound. They warned me that the sheep and goats were not locked up at night and that I might be visited, so before retiring I made a pile of stones convenient to the hand beside my camp bed.

I was indeed visited, and after several misses one stone got home with a satisfying thud—followed by an extraordinary noise, like a mad trombone moaning to the wild west wind. Investigation showed that a goat had put its head right into the large earthenware waterpot provided for me by the chief. In its confusion after being caught in the short ribs by a stone it was waltzing dizzily, partnered by the pot, with its chin and horns impacted at the brim.

A spinal application proved ineffective, and was an ill-judged procedure, especially as the operator was of course wearing only light bedroom slippers. However, manual version without anaesthetic was fairly easy, though when the goat's head was (necessarily) pushed under water the trombone noise gave place temporarily to that of a French horn that has been turned over and over too few times. The pot was unhurt, and the goat showed no sign of birth palsy as it decamped; quite the reverse, I never saw a less spastic goat. Bannister himself would have had difficulty in following up the case.

How lucky we were to have our firstborn in the spring! Lovely, sunny days for drying the nappies and for putting baby out in the garden in her pretty little frocks. It must be so difficult in the winter with a house full of damp washing and waking up in the bitter chill of night to feed her. So many are the disadvantages of winter births that I am surprised that humans, like other more sensible mammals and birds, have not developed a breeding season confined to the spring and summer months. Of course obstetrics would then be a seasonal occupation with a mad rush in the summer followed by unemployment in the winter. The obvious answer would be to practise obstetrics in the spring and summer and paediatrics in the autumn and winter when all last year's production would be getting their coughs and colds. By the time that the last whoops were dying away the first cries of the new crop of babies would be heard in the land. The Royal College could offer a cup for the first delivery of the season.

Unsatisfied, perhaps, with my efforts, the editorial board of the *Ruritanian Journal of Abstracts* has sent me a list of abbreviations. Most of them are plain sailing. I am happily familiar with ml, ecg, i.v., and many others; i.r. (infra-red) nearly sent me to a dictionary until I realised that a hyphen was missing. But the best is C-R (crown-rump). Please, nobody tell me what crown-rump means. Rump is easy, and the C.O.D. confirms my opinion, but crown . . . Is crown a noun? Hardly, for it is apparently applied to the wrong end. Is crown a verb? If so I might arrive fairly soon at a reasonable conclusion. I shall spend many happy hours puzzling it out.

I had to go to the hospital last Sunday so I decided to give our small daughter her first glimpse of white corridors. We set off grandly in the old Riley, which has just celebrated her 19th birthday, and luckily arrived in time for coffee on the ward. Afterwards I handed Frederica over to sister children's and set off on my brief round. About forty-five minutes later we were bowling along home looking forward to our roast lunch but in deep silence; the young mind was obviously impressed.

About a week later Frederica and I were discussing the more serious side of life, which included why it wouldn't be a good thing to take out James's appendix with the carving knife even though he is too young to resist, when she suddenly looked up at me and said: "Daddy, when you go to work in the hospital every day, do you stay in bed all the time too?"

Letters to the Editor

THE POSITION OF NEUROLOGY

SIR,—I am grateful to Sir Francis Walshe for his support in the campaign of the Royal College of Physicians for an adequate neurological consultant service, but I should like to carry his diagnosis a little further. I have no doubt that the economic factor he mentions is one reason why sufficient neurological consultants are not being appointed. But how does it operate? The difficulty arises in connection with regional hospital board appointments and not in the teaching hospitals. The reason is that in a teaching hospital the needs of different departments are discussed in an influential medical committee where all are represented, and the resulting recommendations are normally accepted by the board of governors. But regional hospital boards obtain their advice from an S.A.M.O. and a medical committee which is appointed by themselves and is not representative of all the important branches of medicine. How many such committees include a neurologist? Regional neurological committees may exist, but these are ineffective if they are not represented at the centre. Their advice may not be taken or even sought.

I know that the medical committees of regional hospital boards are devoted and hardworking bodies, but I believe that a medical service cannot be effectively planned unless its organisation includes a comprehensive and representative medical committee at regional hospital board level. This lack is one of the major defects of the present system.

London, W.1.

W. RUSSELL BRAIN.

THE PLIGHT OF SENIOR REGISTRARS

SIR,—In recent issues of *The Lancet* there have been several letters from registrars about the problems of their group. It is a sad commentary on the present state of affairs that most of the writers should have had to remain anonymous. They must feel that their own positions are so insecure and their future so uncertain that they cannot risk being dubbed as "political agitators." This thought must be influencing many registrars, who, as individuals, are surprisingly unvoiced about the disastrous position which still confronts them.

There has been a comparative lull in official thought about senior registrars because of the Ministry decision¹ to allow them to re-apply for their own posts and to permit retention of "transitional posts." This does not mean that there has been any real improvement in the situation. If illustration is needed, the case of the Bournemouth obstetrics post can be cited. For this post—recently advertised—there were 108 applicants of less than consultant status. We can reasonably assume that all these applicants have their M.R.C.O.G. When these numbers are set against the 36 posts in obstetrics that have been advertised in the past two years it is clear that the word "disastrous" is not too strong to apply. In some specialties affairs are better arranged, but the over-all situation is just as grave as that in obstetrics.

For several years sporadic attempts have been made, alternately by the Ministry and by the profession, to solve the senior-registrar problem. The measures so far taken have been only of a temporary nature, but as they have avoided the large-scale dismissal of senior registrars they have been acceptable to regional boards, consultants, and registrars alike. The junior staffing of hospitals is now suffering, partly because young doctors see the mess that their predecessors are in, and will not commit themselves to a similar uncertain future. This is the moment for the Ministry and the profession to agree on a solution to the senior-registrar problem which

will at one stroke set right the wrongs of the present generation and prevent any recurrence of the muddle.

To understand the present position it is necessary to recall briefly some historical points:

1. Towards the end of the war some senior members of the Royal colleges recalled their own struggles after the 1914-18 war. A willing Ministry of Labour was persuaded to give ex-Service grants; the Ministry of Health encouraged the training of large numbers of specialists; willing consultants took on extra staff, and the positions later designated as senior registrar and registrar were rapidly filled.

2. In 1950 the Ministry saw the troubles ahead and attempted to halve the number of senior registrars. The method of doing this and the lack of alternative plans for doing their work caused a political storm and the rejection of the scheme. In its object, however, it was sound.

3. The problem was discussed between the Ministry and the Joint Consultants' Committee, and in 1951 a revised establishment of 960 senior registrars was agreed.² In accepting this figure the Ministry, the consultants, and the registrars made a fundamental mistake. This large number was agreed because it seemed necessary to provide a certain amount of competition for each available consultant post. In addition, the senior registrar was regarded as essential to the working of the hospitals. Here I must quote the words of the joint committee on this subject: "In view of the fact that the senior registrar is a key member of the medical staff . . . the number of posts should not be related too closely to the number of possible openings for consultants, and besides being related to hospital needs they should allow for a proper measure of competition on the Senior Registrar/Consultant level."³ It was estimated that approximately 150 permanent specialists' posts would be available each year, and it was therefore reasonable that something over 200 doctors should be available to compete for them ("the annual outflow"). In theory, the surplus of unlucky senior registrars then disappeared and the following year a new batch, again over 200 strong, were available for the next 150 posts; and so the thing was to go on year after year. In reality, at any given moment and for any given post there are competitors from senior registrars in their 3rd, 4th, and subsequent years, from research-workers, from S.H.M.O.s, and from university lecturers. This false concept of the numbers needed to provide competition has led directly to the present state of affairs. It is now clear that even if the 960 senior registrars were the only competitors there would be far too many to provide fair competition. This is the main error that must be corrected.

Before proposing a solution we must examine the work being done today by senior registrars. No-one can deny that in many cases this is of consultant nature; often the senior registrar has complete control of beds in all but name. It is obvious that a numerically inadequate specialist service is being supported by a grossly exaggerated body of senior registrars. The only possible excuse for getting this work done by men of less than consultant status is to say that they are "training"; but, in fact, we now know that they are training for non-existent positions. This employment of senior registrars in excess of training needs is the main source of cheap specialist labour in the hospital service.

Quite apart from the intense personal problems of the present senior registrars it is essential to the future of the hospital service that this anomaly should be removed. The actions needed are these:

1. The real training needs should be re-assessed in the light of the "competition" fallacy exposed above. The co-operation of the universities should be sought in arriving at a reasonable figure.

2. All positions surplus to the real training needs should be re-assessed. It will be found that the majority of these should be consultant posts. They should be reorganised and re-advertised as such. It might well be acceptable if most of them were made full-time posts with an option of transfer to part-time work after a stated period.

This proper balance between senior registrars and consultants must be such that any man who in future

1. *Brit. med. J.* suppl. 1963, i, 243.

2. *Ibid.*, suppl. 1951, ii, 47.

3. *Ibid.*, suppl. 1951, i, 243.

becomes a senior registrar can be reasonably certain of getting a consultant post within the foreseeable future. The real selection of future consultants must take place at the registrar/senior-registrar level.

The present crisis in hospital junior staffing provides for the first time a separate and vigorous stimulus for solving the senior-registrar problem. Registrars and consultants alike must hope that reason will prevail and swift action follow.

R. M. FORRESTER
Chairman, Manchester
Regional Registrars' Group.

St. Mary's Hospital for Women
and Children, Manchester.

SIR,—My problem is that of a very large number of senior medical and surgical registrars throughout the country. Many of us qualified before September, 1939; we saw the war start and we saw it finish; we took off our uniforms and, since specialists were to be needed in the new health service, we sacrificed some further years in acquiring higher medical and surgical degrees; in this we were most kindly aided by Government grants which fed our families and paid some of the rent.

From then onwards we began to emerge with specialist qualifications. We got registrar posts and we climbed to senior-registrar posts; but this, to most of us, now growing middle-aged, has been the end of all progress and hope. We are extraordinarily well qualified, both by examination and experience, for consultant posts, but such posts are fantastically rare and, unless one has acquired a prominent backer or is known personally to a member of a selection committee (I say this with resignation and not rancour), one has, for practical purposes, no chance at all.

I should like to ask two definite questions:

1. Is it intended to do anything about our plight, or are we to be left until despair and financial hardship have successfully reduced our numbers and thus solved the problem?
2. If the answer to (1) is Yes, can something be expected within twelve months? What may this be?

Two explicit answers here would at least salve some of the heartsickness caused by hope deferred for so many years.

Secondly, I have three suggestions to make in the hope that something can be done quickly:

1. Senior-registrar posts should be made permanent, with protection on both sides, so that the registrar and his family can settle without being uprooted every few years.
2. Their pay should be increased, according to qualifications and experience, by annual increment if necessary, so that it more nearly approximates to that of the most junior consultant or that of the general practitioner or any other responsible doctor.
3. Appointments to consultant posts should conform to some recognisable national plan.

SENIOR REGISTRAR.

SIR,—I have only just seen the letter from "Senior Registrar's Wife" (May 8). Unfortunately there is little likelihood that her appeal will register with those who could help, since through long exposure to such *cris de cœur* they have developed an attitude of uneasy *laissez-faire*. I refer of course to the consultants. It is distressing to have to criticise senior colleagues whom in other respects one holds in esteem, and I should like to excuse in advance the outspokenness of my ensuing remarks on the grounds of desperate urgency.

The present so-called surplus of senior registrars is an isolated phenomenon based on a series of factors so well known as not to need recapitulation, and which we all hope will not recur. The pressure from below has ceased, and it seems likely that the situation will have responded to the law of supply and demand in a few years' time. In the meantime, however, there exists an unfortunate group of some hundreds of senior registrars, many of them excellently trained and qualified, who are unable

to find permanent positions. It is difficult to understand, rationally, why this should be so. Can there really be a surplus of senior registrars when most of them are still doing a full day's clinical work? Is it not possible for them to continue to do that work under conditions of security of tenure? In my opinion two factors contribute greatly to the magnitude of the registrar problem.

The first is that too much specialist work, especially in surgery, is still being done by general practitioners.

I know personally of several such instances. I have the highest regard for the G.P. as a G.P., who has a full-time job calling for special skills and knowledge. Few, however, have had adequate surgical training by modern standards, and fewer still work in an environment in which surgical knowledge and technique can be kept at top efficiency. At a time when some hundreds of competent surgeons face professional extinction there can be no place for such surgical dabbling by privileged amateurs. Only the senior consultants, however, could put an end to this abuse. The reasons why they do not do so are obvious to those in contact with the situation, and are not particularly creditable. Most consultants whom I know personally agree in private that G.P. surgery is undesirable, but they are anxious not to offend the often influential men who practise it. The approach employed seems to be the "tactful" one of allowing the G.P. surgeon to die a natural death. Unfortunately we senior registrars face an even more imminent demise.

The second factor is the inertia which obstructs any move to increase the specialist force.

Lack of money is the extremely disingenuous excuse often given. Can anyone believe, however, that the Government, if so urged by the consultants, would balk at the relatively small financial outlay involved in promoting a series of fourth-year senior registrars to part-time consultants? Most hospitals with which I am acquainted could well substitute one or two extra consultants for an equivalent number of senior registrars. Such a move, if applied generally, would virtually solve the registrar problem. Some regional boards, to their everlasting credit, have already taken such steps. Others are lagging, and in our unfortunate position we registrars cannot entirely rid ourselves of the suspicion that the established consultants are influenced in certain cases by a desire to avoid competition in the restricted field of private practice. It would be charitable to assume that this motivation, where it exists, is subconscious.

The ball is with the consultants, many of whom would do well to consider how they themselves might fare, today, if they were applying for their own posts. We senior registrars are not mendicants or misfits. We do not ask for feather-bedding, or for automatic Army-style promotion. All we seek is a fair chance to build our careers.

I dislike unsigned letters, but since my name is at present before committees I would ask your permission, Sir, to remain anonymous.

TRAVELLING FELLOW.

EFFECT OF CONTROLLED HYPOTENSION ON CEREBRAL FUNCTION AND CIRCULATION

SIR,—The elevation of the head in a tilted or upright position reduces the blood-pressure in the brain by 2 mm. Hg for every inch of vertical height above heart level. When vertical, the cerebral blood-pressure in the average adult is approximately 30 mm. Hg lower than at heart level.

In your issue of June 5 Dr. Saunders claims that cerebral function in conscious healthy adults is only slightly impaired when the blood-pressure in the erect posture falls to 60 mm. Hg (presumably measured on the arm at heart level). In two subjects pressures lower than this (45–50 mm. Hg) were apparently without effect on cerebral function. As the cerebral blood-pressure in these subjects must have been in the region of 20–30 mm. Hg during these observations, it is evident that the brain has an enormous safety margin in its vascular supply.

From these figures it is reasonable to assume that the tilted position employed by some anaesthetists for controlled hypotension is reasonably safe, particularly when associated with the decreased cerebral oxygen consumption of anaesthesia.

SYNDROMES OF RHEUMATOID ARTHRITIS

SIR,—Dr. Kersley's article last week is one of the most useful that has appeared in this field for a long time. My clinical experience is in close agreement with his.

I have had a similar proportion of cases which at the outset clinically resembled the classical picture of rheumatic fever more closely than that of rheumatoid arthritis, but eventually developed into typical rheumatoid arthritis. I have not found the therapeutic test of giving salicylates useful, as some of the cases responded well to salicylates at first.

I agree that monarticular cases of rheumatoid arthritis do occur and that the differential diagnosis from tuberculous arthritis is difficult on clinical grounds. The diagnosis is a dangerous one, and should not be made until the chest has been radiographed and a synovial biopsy done; even then the diagnosis should be kept under continuous review. I was recently consulted by a patient who had been attending a rheumatic clinic for some months with so-called monarticular rheumatoid arthritis. At the first consultation a chest radiograph revealed a miliary appearance in the lungs. The patient has since died.

I have also seen several cases of advanced rheumatoid arthritis without pain. Possibly these cases are commoner than Dr. Kersley's experience and my own would lead us to expect, as the patients consult their doctors late in the disease and may pass their lifetime without attending a hospital clinic. Two of my cases were seen in domiciliary practice, for other general medical causes, on their death-beds. Although I agree with Dr. Kersley's general impressions of these fascinating cases, I cannot agree with his argument that because two cases developed pain late in the disease therefore any question of the general pain threshold playing a part is ruled out. In the single case reported by Clark¹ the cutaneous pain threshold was measured and found to be greatly elevated. I have not been able to collect enough cases to form a reliable assessment. It would be interesting to hear the experience of others, and especially to hear of any cases in which the general pain threshold has been measured. This is a most fascinating problem both from the point of view of discovering the fundamental mechanism of the phenomenon, and from the point of view that these cases reveal one of the many fallacies in using tenderness as a test for assessing therapy in rheumatoid arthritis unless the general pain threshold is measured at the same time.

Dr. Kersley's article adds to the belief that astute and careful clinical observation still has a large contribution to make in the elucidation of fundamental problems in rheumatism.

Filmwell, near Wadhurst,
Sussex.

G. E. LOXTON.

SIR,—I have read with interest Dr. Kersley's article and particularly his account of cases with acute onset resembling rheumatic fever.

As a cardiologist I have always held the opinion that true rheumatoid arthritis does not lead to rheumatic endocarditis (mitral or aortic valvular disease). I note that in Dr. Kersley's series of 750 cases of rheumatoid arthritis only 1 developed carditis resembling that of rheumatic fever.

In this case which he describes (case 1) mitral and aortic disease was noted four months after the development of acute rheumatism and pericarditis at the age of 25.

1. Clark, C. J. M. *Ann. rheum. Dis.* 1951, 10, 105.

Dr. Kersley does not state whether the mitral disease was mitral stenosis. If this was so it is most unlikely that the valvular disease arose from the acute rheumatic infection four months previously, as mitral stenosis usually takes much longer before it becomes manifest—usually two to five years at the earliest. The valvular disease is much more likely to have originated from an old rheumatic endocarditis in childhood. There may be no history of rheumatic infection at that time, and a rheumatic endocarditis often passes unrecognized and unsuspected until valvular disease becomes manifest years or decades later, as is well known. A further attack of acute rheumatism, as in Dr. Kersley's case, will often make it manifest. The commonest age at which rheumatism attacks the heart is from 5 to 15 years and it very rarely does so after 20 years.

Rheumatoid arthritis is a not uncommon disease in young people in the 20–40 age-group, and this is also the age-group when rheumatic endocarditis is likely to become manifest following a rheumatic infection in early life. It would, therefore, be expected that rheumatoid arthritis with endocarditis will be found in some cases, but this does not at all imply that the endocarditis is the result of the rheumatoid arthritis. I quite agree with Dr. Kersley that "rheumatoid arthritis and rheumatic fever are normally quite distinct, being completely different in clinical course, cardiological complications, prognosis, and therapy"; but I do not agree that "occasional border-line cases should make us wary of regarding them as separate entities." I still believe that they are separate entities, though they may co-exist.

Blackpool.

MAURICE NEWMAN.

VOMITING AND REGURGITATION DURING ANÆSTHESIA

SIR,—I was very interested in last week's article by Dr. O'Mullane on the foot-down tilt during the induction phase of anaesthesia for the patient who may have a full stomach. This is a technique that I have found very safe and satisfactory, and I would press for its wide adoption as a standard method for this type of case.

The method as described by Morton and Wylie¹ depends for its effectiveness on the prevention of: (1) active vomiting, by the administration of thiopentone and a relaxant; and (2) passive regurgitation, by ensuring that the pharynx is well above the level of the stomach. In my opinion this method is the safest way of inducing anaesthesia in patients with intestinal obstruction or other causes of the full stomach.

In one respect only would I differ from the observations of Dr. O'Mullane—namely, that vomiting may occur after sleep has been induced but before the relaxant has had time to take effect. Thiopentone depresses the central nervous system so rapidly that the patient is carried below the stage of vomiting before it has had time to develop, and provided the airway is kept completely clear there is no danger of aspiration of gastric contents into the hypopharynx.

The traditional method in these cases—namely, nitrous oxide, oxygen, and ether—possesses two main disadvantages: (1) a relatively low oxygen content in the inspired mixture; and (2) a highly irritant vapour which may on occasions, particularly in inexperienced hands, lead to laryngeal spasm. This in turn may cause aspiration of gastric contents into the hypopharynx, usually aggravated by the head-down tilt adopted at such times, and a very vicious circle is initiated. The resultant anoxia may be highly dangerous to an elderly, ill patient with hidden coronary artery disease and a myocardium ill suited to such an insult. Surely it is more rational to ensure that the gastric contents never reach the pharynx than to rely on the natural reflex ability of the cords to prevent foreign material being aspirated into the lungs—a reflex which may in itself be dangerous.

1. Morton, H. J. V., Wylie, W. D. *Anæsthesia*, 1951, 6, 190.

This method does not absolve the anaesthetist from ensuring as far as possible that the stomach has been emptied through a suitably wide tube, but even with the utmost care some material may remain in the stomach. One important point must be borne in mind when using the method: it is more important than ever that the anaesthetist should be fully aware of the danger of inducing hypotension in the shocked or oligæmic patient by giving too large a dose of thiopentone.

MERIT AWARDS

SIR,—The council of the Regional Hospitals' Consultants and Specialists Association is aware that throughout the country there is considerable disquiet at the manner in which merit awards are distributed. This disquiet is no doubt due in the main to the overt secrecy which enshrouds the subject. Since the early days of the National Health Service there have in many regions been no local consultations and little or nothing is known of how recommendations are made or considered. In many areas local advisory committees have not been further consulted and, indeed, in some cases have been summarily dissolved.

At its meeting on June 3 the council of this association accepted the following resolution put forward by one of its constituent bodies:

"The Council of the Regional Hospitals' Consultants and Specialists Association is of opinion that in the granting of Distinction Awards the Awards Committee should consult local medical opinion, and that this could best be done through small Regional Advisory Panels of Consultants elected by the Consultants in each Region."

HYPERTHYROIDISM AND MYASTHENIA GRAVIS

SIR,—In their interesting article (May 8) Dr. Maclean and Dr. Wilson refer to the antagonism between these two disorders where they co-exist. They note that appropriate treatment for the thyrotoxicosis aggravates the myasthenia gravis, whereas in patients with myasthenic symptoms produced by thyrotoxicosis these symptoms are relieved by such treatment.

They suggest that thyrotoxic myasthenia may be due to the rapid destruction or defective production of cholinesterase at the neuromuscular junction, possibly as the result of a high blood-thyroxine content. Elsewhere they make the apparently contradictory suggestion that a high blood-thyroxine level may cause deficient production or too rapid destruction of acetylcholine.

Does the first of these suggestions provide a clue to the phenomena observed? If in thyrotoxicosis acetylcholine is present in excess owing to the absence of adequate amounts of cholinesterase, might not the myasthenia that may supervene in such a case be due to the persistent effects of unhydrolysed acetylcholine producing neuromuscular blocking? Feldberg¹ found that an excess of acetylcholine produced a spread of the depolarisation current from the motor end-plate to adjacent parts of the muscle-fibre. Might the tendency to persistence of acetylcholine, though in less amounts than would produce neuromuscular blocking, account for the fine tremors of the voluntary musculature in thyrotoxicosis?

On this hypothesis the alleviation of symptoms of myasthenia gravis in thyrotoxicosis would be explained by the relatively small amounts of cholinesterase at the nerve-endings sparing the acetylcholine to some extent.

PERIPATETIC PRACTITIONERS

SIR,—May I strongly endorse Dr. Forbes's advice (June 5) about the importance of doctors keeping their defence societies and the General Medical Council informed of a change of permanent address?

There is another disadvantage in failing to do so which he does not mention. The Medical Protection Society sometimes hears of impending litigation which may involve a member whose present whereabouts are unknown to us, and delay in establishing contact with him at an early stage may later seriously prejudice his legal position or that of his colleagues as the action matures.

The difficulty in tracing a woman practitioner may be further increased when she does not inform her defence society or the Registrar of the G.M.C. that she has changed her surname as well as her permanent address!

Medical Protection Society,
Victory House,
Leicester Square, London, W.C.2.

ALISTAIR FRENCH
Secretary.

MENTAL CARE

SIR,—The articles by Dr. Bickford (May 1) and Dr. Ling (May 29) and your leader (May 29) raise many important issues for the planning of the mental health services. While with enthusiasm and well-directed effort much can be done to improve the situation, neither the well-known and already widely practised methods of rehabilitation so eloquently presented by Dr. Bickford nor the highly successful approach devised by Professor Querido will entirely solve the problems which mental illness presents. One does not want to be pessimistic at this stage, but it is important to realise the limitations imposed by the clinical, social, and cultural complexities inherent in the problems of mental illness. The mental hospitals' deficiencies do not always account for not achieving the desired complete remission of all symptoms. One must agree with Dr. Bickford, however, that most patients with psychiatric disorder show a very high capacity for social rehabilitation and an ability to live with their symptoms. More research is required into the causes of our successes and failures before we can say what results can be expected from this new approach.

Faced with the serious overcrowding, which burdens and often almost paralyses the proper functioning of the mental hospitals, my colleague, Dr. D. H. Bennett, and I paid a visit to Professor Querido and his colleagues in Amsterdam a little while back. We have spent some time and thought on the problems that could arise, for our own mental hospital and the community it serves, with the introduction of such a scheme as that outlined in Dr. Ling's article and your leader.

The Amsterdam scheme was developed and is operated by the local health authority, of which Professor Querido, a psychiatrist, is also the chief medical officer of health. The mental hospital under these circumstances remains without its own outpatients and other aftercare services, and we came to the conclusion that this conception was not entirely satisfactory. We therefore suggest that the scheme will require modifications in this respect. For our population area of 600,000 we should require for such a twenty-four-hour psychiatric service, apart from transport, about six additional psychiatrists and six psychiatric social workers. Even with this increased number of staff, if these were available, the saving not only in the adult mental health field but also in the departments of child care and education would be very considerable.

All this might sound unduly cautious. It is, however, certain that many of the new principles at present under discussion, adapted to this country's needs, will yield promising results. We do not mean to leave your readers

under the impression that no more capital need be spent on the mental hospitals, whose buildings are out of date and whose equipment is inadequate to meet the needs of patients. Without extra staff or resources it has, however, proved possible in our own case, by applying some of the principles of the Amsterdam scheme, to reduce the overcrowding to an extent which encourages us to plead for a fuller and realistic development of preventive and after-care services. Whilst this cannot be offered as a solution to the problem of the cause and cure of mental illness, it would undoubtedly improve the pattern of psychiatric care.

Netherne Hospital,
Coudsdon, Surrey.

R. K. FREUDENBERG
Physician-superintendent.

PREOPERATIVE ANÆSTHETIC OUTPATIENT CLINIC

SIR,—The interesting article by Dr. Loder and Dr. Richardson (June 5) draws attention once again to a leading advantage of such clinics; the number of surgical beds available is increased by preliminary investigations and treatment in the outpatient department.

Glycosuria can be stabilised, dental sepsis cleaned up, the anæmic patient given a normal hæmoglobin level by simple therapy, and a report obtained from the chest physician on the patient with tuberculosis. A history of angina of effort or coronary occlusion can at least be noted, putting the anæsthetist on his guard, while in non-urgent cases the advice that the operation should be postponed may prevent a catastrophe.

Less important functions of the clinic include the treatment of obesity by low-calorie diet, with frequent supervision and encouragement (or censure of the uncoöperative). I have seldom met a surgeon, and never an anæsthetist, who does not prefer a reasonably thin patient to a fat one. When thyroidectomy is contemplated, we examine the vocal cords by indirect laryngoscopy. It is wise to record the fact that both cords move normally before anæsthesia and operation.

I notice that some hospital authorities are encouraging the formation of these clinics within the existing establishment. This is asking a good deal of the anæsthetists, and seems a little unrealistic. The work, like all outpatient work, is time-consuming and fatiguing, and requires at least one whole session weekly.

In conclusion I should like to re-emphasise the medicolegal responsibility of the anæsthetist to his patient. Thorough pre-anæsthetic investigation and examination gives the anæsthetist an assurance which is most valuable and may be of great importance if anything goes wrong. Sometimes when feeling somewhat paranoid I think of Dr. Johnson:

"It is the fate of those who toil at the lower employments of life to be exposed to censure without hope of praise; to be disgraced by miscarriage or punished for neglect when success would have been without applause, and diligence without reward."

As anæsthetists we should take all reasonable steps to ensure that everything is done to make the anæsthetic and operation as safe as humanly possible.

General Hospital,
Southend-on-Sea.

J. ALFRED LEE.

SIR,—Dr. Lee is to be congratulated on his foresight and enterprise in initiating in 1949 the idea of an anæsthetic outpatient clinic.¹

It has been said that a new idea is the most potent antigen known to science, and it is not surprising that as yet relatively few of these clinics are in existence. It was refreshing to read in January, 1952, of the clinic established at St. George's Hospital, London, by Green and Howart,² and in your issue of June 5 of the one run by Dr. Loder and Dr. Richardson at the Peterborough

Memorial Hospital. This was referred to as a pre-operative clinic; but, having had a similar type of clinic one afternoon a week at the Hull Royal Infirmary for the past three years, I find it is also of value in seeing patients postoperatively, particularly those on whom one has done diagnostic and therapeutic nerve-blocks and those subjected to specialised techniques such as controlled hypotension.

The principle of the anæsthetic outpatient clinic is sound; it can be managed successfully, and I believe one should form an integral part of every anæsthetic department.

The anæsthetist of the future must be not merely a technician but also a physician, and it is already possible to obtain the M.R.C.P.E. with anæsthesia as the special subject and the F.R.C.P.(C.) with emphasis on anæsthesia.

Hull.

W. N. ROLLASON.

SECULAR HUMANISM

SIR,—Dr. Joseph Walker (May 15) seeks to discredit humanism by saying it is incompatible with Christianity, in much the same way that McCarthy has succeeded in discrediting liberalism by insinuating that it is un-American. Just as American liberals must now cast about for another word to describe the man who conceives his own political interest as bound up in that of society as a whole, so will humanists, if Dr. Walker's "smear" sticks, have to find another word for the deliberate rational quest of human welfare. Thus is our language littered with the untouchable corpses of contaminated words, like the mounting waste of material and tools rendered permanently and lethally radioactive in the production of the bombs.

In maintaining that Communist society is a natural outcome of the humanist tradition he confuses the latter with materialism. The deliberate quest of human welfare does not produce cruel systems, such as Russian Communism or the Spanish Inquisition, which arise from the enforcement of a creed ostensibly in the interest of the majority but in reality out of hatred for the minority. Hatred of the bourgeois is disguised as concern for the proletariat, hatred of heretics disguised as concern for their souls.

By using a revered word, Christianity, with which he tells us humanism is incompatible Dr. Walker seeks to darken the meaning of the latter. Unfortunately he does not tell us whether by Christianity he means the teaching of Christ or that of the Church. Humanism in no way conflicts with the former, but it is of necessity secular—i.e., free of the Church—for it hopes to influence Hindus, Moslems, Christians, Jews, in fact humanity. If by Christianity he means the teaching of the Church then he can hardly expect its firm espousal, which he recommends to the West, to be followed with enthusiasm by our brethren in Asia and Africa. Unencumbered with the elaborations of Alexandrian and European theologians, the teachings of Jesus, an individual and incidentally an Asian, stand far greater chance of acceptance.

Humanism preaches the need for universal love and the conquest of hate but it does so through the method and terms of science, partly because science is one of the few products of Western culture which command universal respect. But more important is the fact that science is the method of securing maximum agreement, with its appeal to the evidence of this world rather than to the authority of dead theologians conjecturing about the next.

The Christian Church has had many hundreds of years in which to persuade mankind to accept its doctrines, yet its failure to do so is continually blamed on mankind (a product of God) rather than on the Christian Church (a product of men). It is hardly likely to succeed in the few decades that are left to us to choose between total destruction and a deliberate rational search for agreement

1. Lee, J. A. *Anæsthesia*, 1949, 4, 169.

2. Green, R. A., Howart, D. D. C. *Ibid.*, 1952, 7, 40.

among all men, at present divided by their adherence to man-made religions, philosophies, and nationalities.

The appeal of the Church is waning because of its insistence that man must adapt to its doctrine rather than vice versa, because of the denial of the biological nature and needs of man involved in much of its mythology and ethics, because of its circumvention rather than incorporation of the scientific attitude, and lastly because of its complacency towards the problem of overpopulation—almost as urgent a danger as are the bombs.

A. G. RICHARDS.

SURGICAL TREATMENT OF ACUTE OSTEITIS IN CHILDHOOD

SIR,—By describing a simple but possibly very useful modification of technique as “abandoning the method so strongly recommended” Professor Trueta suggests (June 5) that I have been disillusioned in my early preference for aspiration of pus in osteomyelitis as opposed to open operation. Far from it: to improve a technique is not to abandon it, and the use of lavage through two (not several) needles may prove to be a way of getting over the main disadvantage of aspiration, the need for frequent repetition in some cases. The results continue to be as good as before, that is to say as good as those reported from Newcastle seven years later.

The demand for an “objective” report of our late results is reasonable enough. So as to avoid any suspicions that our accounts of our cases may be subjective Professor Trueta is hereby given an invitation to join Dr. Bodian and myself in a review of them at any date that suits him.

As to our original argument, those interested in medical polemics will find it rewarding to look up the correspondence.¹ It ended with an unanswered challenge to state in what ways the final results of open operations are better than those of aspiration; it is obvious enough in what ways they are worse.

DENIS BROWNE.

EARTHING ELECTROCARDIOGRAPHS

SIR,—A rising water-main is usually considered the most efficient earth for electrocardiographs that require earthing, but one is not always readily available; in such cases the earth-wire of a three-pin plug is often a satisfactory alternative. It is an advantage to be equipped for using any of the several standard-size plugs and I have found the following arrangement useful:

The earth-pin of a three-pin 2-amp. plug top is fitted with a single wire about 6–8 in. long, the other end of which is fitted with a crocodile clip with screw terminal. This is connected with the earth-wire of the electrocardiograph. The other two pins of the three-pin 2-amp. plug top are fitted with two wires (twin flex) to carry the A.C. supply to the instrument and with a terminal (5-amp. two-pin socket or bayonet cap) that can be connected with the terminal of the A.C. supply wire of the cardiograph. This arrangement makes it possible to use a three-pin 2-amp. plug for providing the A.C. supply and earthing of the instrument.

By adding a 5–2-amp. three-pin adaptor, a 5-amp. three-pin plug can be used, and by the further addition of a 15–5-amp. three-pin adaptor (M.K. standard, protected by a 5-amp. fuse) a 15 amp. three-pin plug can be used.

With this outfit, which can be put together easily and cheaply, one is equipped to use any of the three standard sizes of three-pin plugs (15-amp., 5-amp., 2-amp.) for providing the A.C. supply and the earthing. This arrangement, however, cannot be used with the more recent 13-amp. square plugs, which are fitted in some new houses, but a plug top of these square plugs can easily be fitted with the necessary wires and terminals.

THE DISABLED

SIR,—In your leader of June 5 you state that the Central Council for the Care of Cripples finds that some employers make up their quota of disabled by engaging people whose disability does not hamper them for the work in hand. Surely it is just this that needs to be done. The more disabled people that are in jobs congenial to both themselves and their employers, the smaller the problem of employing disabled people.

In occupational health it is necessary to achieve a harmony between the individual and his working environment. A deaf man is better suited to work in a boilermakers' shop than one with acute hearing (in this instance the disability is a positive advantage). A person with a history of bronchitis should not be employed in a silica brickworks or as an electric-arc welder but will probably be well suited to assembly work in a toy factory as long as there is no soldering involved. With a little training a blind person is perfectly able to operate a telephone switchboard.

The essence of employing disabled people is to achieve this harmony, and the only way it is likely to be achieved is by studying the problems and applying the results in the factory. In medicine generalisations are never satisfactory, and in the last resort these problems always boil down to the individual case and one or two possible jobs in any particular factory. It should always be remembered that the main function of industry is to produce, and good production results from the intelligent use of men, machinery, and materials. If industry uses disabled men intelligently it adds an important social function to its main purpose.

Dunvant,
near Swansea.

G. G. MATHEW.

SIR,—In your admirable leading article there is one statement with which I do not find myself in agreement. You say, in the sixth paragraph, “a bank clerk with a gastric ulcer . . . is not disabled and should not count towards the quota.”

Why not? Surely the intention of the Act was to safeguard our weaker brethren. Where mechanical aids decimate staffs (as, I am informed, may happen), will not some remote managing director in the city say: “Yes, now we'd better get rid of Jones in the Little-town Branch first, he's lost a fair amount of time in the last few years.” And so poor Jones, unprotected, goes and his ulcer increases another few millimetres in diameter. Or perforates.

Again, “the regulations might well be tightened . . .” This is a fair comment, but how is it to be done? Those of us in industry know that registration under the Act does not represent a true picture of the extent of disabilities. We can all think of workers whose justification for registration is slight; we know that the motives which cause a man to register are many and various. But, by and large, the definition of a disabled person is fair, just, and reasonable, and if it be interpreted in the liberal spirit of the Act no injustice will be done.

It seems to me that the more practical approach would be to raise the quota for industry generally or to apply differential quotas. The latter solution may not appeal because of the inevitable controversy and dispute which it would arouse.

Finally, Sir, one of the functions of the industrial medical officer is to fit the disabled worker, where possible, into a job in which his disability is of no account and he can work on equal terms with his fellows. But that does not mean to say that the disabled worker has the same potential mobility as his fit colleagues. Should hard times come again, the mobility of labour is going to be much more important than it has ever been since the far-off days of 1939.

Rotherham.

R. McL. ARCHIBALD.

DIET AND CORONARY DISEASE

SIR,—After reading Professor Duguid's riposte to Dr. Leitner and Mr. Daw I turned to the very next page of your June 5 issue to find the photograph of the late Sir James Spence and, opposite, his words: "Techniques have their place in medicine, but they are not medicine."

Surely neither Professor Duguid in his laboratory experiments, nor Dr. Leitner in quoting statistics, presume to do more than stimulate speculation on this subject by "techniques" which in both instances could be used to confound their own deductions.

To a practising clinician coronary disease and atherosclerosis spell ageing—wear and tear of the cardiovascular system: "A man's as old as his arteries." He may be mystified why patients with similar heredity, habits, and environment should present at times vastly different rates of ageing, but he does come to see and know as a clinical fact that cardiovascular wear and tear is associated with the seven fat years rather than the seven lean ones, that the seven fat years do not mean merely increased fat percentage of total calories, but increased percentage of mechanical transport, sedentary occupation, and nervous as opposed to physical exertion. On this broader base-line Dr. Leitner's graph assumes a more clinical flavour.

Likewise it is of remoter significance to know how a certain lesion is laid down or how it can be mimicked in dog or rabbit than to appreciate why such a lesion means myocardial infarction in one and not in another—a problem that Professor Wenckebach's series of 5000 necropsies leaves unanswered.

London, W.1.

W. PINNINGTON JENSON.

APPOINTMENTS SYSTEMS

SIR,—Your annotation last week on the "reasonable, practical, and kindly duty of arranging appointments systems for outpatients" maintains that failure to provide such a system is due to lethargy. There are, however, under certain circumstances valid arguments against an appointments system, and as such apply to one of the hospitals in Leeds Group A, I would like to indicate them.

Ideally appointments are the perfect system. In practice when such a system is instituted the consultant decides the maximum number of patients he can see at each session compatible with giving each a really comprehensive examination. Inevitably in some departments this number is less than was seen in the pre-appointment days, and as a result a waiting-list is soon built up and the patient may have to wait several weeks or even months for an outpatient appointment. There are two possible ways of preventing a waiting-list accumulating. More consultants could be appointed, but this does not seem likely to happen in the near future. Alternatively the consultants could see sufficient numbers of patients at each session to clear the list of patients wanting appointments each week. This would lead to a lowering of the

standard of work but would be counterbalanced by the patient being seen within a few days.

In Leeds there are two main outpatient departments: the General Infirmary, where an appointments system has been working very efficiently for some years but where, at times in some departments, outpatients may be kept waiting several weeks for an appointment; and the Public Dispensary, which maintains the "open door" system whereby patients are sent up without a previous appointment and seen if possible the same day (occasionally on very big days they may be referred to the next session). Pressure has been brought to bear on the dispensary to adopt an appointments system. Before any action was taken the local medical committee was consulted and was strongly opposed to any appointments system. The general practitioners maintained that for many patients it was much less deleterious to wait an hour or two on a given day in outpatients than to wait several weeks for an appointment before they ever go to the hospital. The patients appreciated this when it was explained to them.

It is obvious that in Leeds we are lucky in having the two systems working side by side. Where a case is not urgent and the general practitioner wants to send him to a special consultant at the infirmary he can have an appointment. On the other hand for none-acute but relatively urgent conditions the patient can go at once to the dispensary, though he may have to wait a bit when he gets there. For subsequent visits appointments are made at both hospitals.

This letter is a plea against generalisations, emanating from a central authority, which, though excellent in theory, may in certain circumstances do the patient more harm than good.

F. F. HELLIER

Chairman of the Medical Advisory Committee, Leeds Group A Hospitals.

ACTION OF ISONIAZID AND ANTIBIOTICS ON NOCARDIA MADURÆ

SIR,—The effect of antibiotics on several human pathogenic fungi has lately been reported.^{1 2} We should like to report a study of the effect of antibiotics in vitro, against *Nocardia maduræ* (previously known as *Actinomyces maduræ*), the causative organism of Madura foot, which is prevalent in parts of Southern India. Antibiotics have been used in the treatment of this disease but results have been inconclusive.

In our experiments a strain of *Nocardia maduræ* was grown in Ashby's mannitol broth (medium A) and glucose-peptone broth (medium B),³ and assay was made by the serial-dilution method. The assay tubes, each containing 10 ml. of the final broth, were incubated at 37°C for up to three weeks, and the activity of the antibiotics was determined from measurements of growth. The results given in table 1 indicate the potency of different antibiotics in varying

2. Waksman, S. A., Romano, A. H., Lechevalier, H., Raubitschek, F. Bull. World Hlth Org. 1952, 6, 163.
3. Ashby, S. F. J. Agr. Sci. 1907, 2, 38.

TABLE I—EFFECT OF DIFFERENT ANTIBIOTICS ON *Nocardia maduræ*

Concentration (µg. per ml.)	Streptomycin		Chloramphenicol		Aureomycin		Penicillin		Actidione		Patulin		Polymyxin		Penicilloic acid	
	A	B	A	B	A	B	A	B	A	B	A	B	A	B	A	B
0	++++	++++	++++	++++	++++	++++	++++	++++	++++	++++	++++	++++	++++	++++	++++	++++
10	+++	+	++++	++++	-	-	++++	++++	++++	+++	++++	+++	+	-	+++	±
25	+	±	+++	++	-	-	++++	++++	++++	+++	+++	++	-	-	++	±
50	-	-	++	±	-	-	++++	++++	++++	++	++	++	-	-	+	-
75	-	-	-	-	-	-	++++	++++	++++	++	++	-	-	-	±	-
100	-	-	-	-	-	-	++++	++++	++++	++	+	-	-	-	-	-

++++ = good growth. +++ = medlum. ++ = poor. + = very poor. ± = doubtful. - = no growth.

TABLE II—EFFECT OF ISONICOTINIC ACID HYDRAZIDE AND STREPTOHYDRAZID ON *Nocardia madurae*

Concentration (mg. per ml.)	Isoniazid		Streptothydrazid	
	A	B	A	B
0	++++	++++	++++	++++
0.25	+++	++++	—	++++
0.50	+	++++	—	++++
1.0	—	++++	—	++++

concentrations against the test organism. All experiments were carried out in triplicate and the mean values recorded.

Isoniazid and streptothydrazid⁴ (a condensation product of isoniazid and streptomycin) were similarly tested, but limiting concentrations were much higher than those used in the case of antibiotics. The same experiments were carried out, and the results are given in table II.

It was shown that streptomycin and aureomycin might be successful in clinical use and that polymyxin is also worth clinical trial. Actidione and patulin, two antifungal agents, had no promising inhibitory action while penicillin, although widely used, had practically no action against test organism. Streptothydrazid was effective in concentrations of 0.25–1.0 mg. per ml. and isoniazid inhibited growth only at concentrations of 0.5–1.0 mg. per ml.

The absence of inhibition by isoniazid and streptothydrazid in medium B, is difficult to explain on the available data, and further work on this point will be reported elsewhere.

Our thanks are due to Dr. A. Chakravorty, of the School of Tropical Medicine, Calcutta, for the strain of *Nocardia madurae*, and to Messrs. Chas. Pfizer for pure samples of antibiotics.

ARTHROPLASTY v. ARTHRODESIS

SIR,—It is very wrong of Sir Reginald Watson-Jones (June 12) to use such a phrase as “the results [of arthroplasty] can be good if the operation is done well, and most recent failures have arisen not because the operation was bad but because the operation was done badly.” Surely he does not really mean thus to insult those of us who have had reason to doubt the efficacy of recent methods of arthroplasty of the hip-joint. The investigations reported by Dr. Margaret Shepherd,⁵ are based upon work carried out in half a dozen centres by a number of competent surgeons in 500 cases. The conclusion is that too high a proportion of cases have results which do not stand up long enough to stress of normal character. The operation and after-treatment, which costs the State at least £200 and has only a 50% chance of giving satisfaction for five years, must be regarded with the gravest doubt. It is probable that the results are even worse than my figures suggest. Such would not be tolerated by any general surgeon treating hernia or gastric ulcer.

To say that the bad results of surgery are the results of bad surgery is a half-truth that can be quite untrue. Many surgeons regard gastro-enterostomy as a bad operation even though it has produced some excellent results with a low mortality; but their opinion is not based upon the fact that occasionally the operation was badly done. What right has Sir Reginald to stigmatise the work of his professional brethren, when unsuccessful, as “done badly”? If the result of such criticism should be to prevent other surgeons from allowing an honest inquiry into their results, he will have done surgery a disservice.

SURGERY OF THE THYMUS GLAND

SIR,—In his article last week Mr. Geoffrey Keynes refers to some of the evidence for the existence in myasthenia gravis of a circulating curare-like substance, and suggests the thymus gland as a source.

The established neuromuscular block of myasthenia undoubtedly has the properties of a competitive inhibition or curare type of block. Thus, it is reversed by substances having only an antagonism for competitive block in common (e.g., neostigmine, adrenaline, and tetraethylpyrophosphate), it is potentiated by *d*-tubocurarine, and it is greater on higher (tetanic) rates of nerve discharge.

It is, however, a far cry from establishing the presence of a competitive inhibition block in myasthenia to suggesting a circulating curare-like substance of thymic origin as the cause of it, particularly as this would not explain many of the clinical and experimental findings peculiar to myasthenia. For instance, it is difficult to see how the circulating curare-like substance alone could produce weakness confined to isolated peripheral muscles such as occurs in some forms of myasthenia. Further, it can be observed both clinically and electromyographically that myasthenic weakness, unlike that produced by *d*-tubocurarine, is a progressive type of transmission block, requiring a period of exertion to produce it, and reversing on relaxation.¹ In fact, the whole clinical and electromyographic picture is that of a cumulative neuromuscular block dependent on the arrival of nerve impulses and totally unlike the effect of the administration of muscle relaxants of either the competitive inhibition or depolarising type to conscious human subjects.

Similarly, experimental evidence does not support the concept of a circulating curare-like substance as the cause of myasthenic weakness. Neither measurements of the relative sensitivity of different myasthenic muscles to *d*-tubocurarine² nor the reactions of such muscles to decamethonium salts³ lend support. The latter consists in either tolerance to or the production of a competitive inhibition block by decamethonium iodide, a substance which normally acts as a pure depolariser. This phenomenon is explicable only in terms of local changes at the motor end-plates of myasthenics.

Finally, attempts to obtain direct evidence of the presence of a substance in the serum or thymus tissue of myasthenics, capable of depressing nerve-muscle preparations, have been numerous⁴ and as contradictory as the results of thymectomy appear to be. In this connection, we note that Mr. Keynes states: “these thymus glands can be made to yield a potent extract which repeats on the laboratory bench the nerve-block effect ordinarily obtained with tubocurarine.” In fact, according to the publication he quotes,⁴ thymus extracts, while capable of depressing the response of nerve-muscle preparations to indirect stimulation, have not been shown to leave the response to direct stimulation unaffected, nor to produce a depressed response capable of reversal by neostigmine or worse on high rates of nerve stimulation. Thus, thymus extracts from myasthenics have not been shown capable of producing the competitive inhibition or curare-like neuromuscular block which is characteristic of the condition.

In summary, we suggest that the available clinical and experimental evidence indicates that the weakness in myasthenia gravis is due to local changes at the motor end-plates, and is not due to a circulating curare-like substance of thymic origin.

Obituary

ANGELO LOUIS PETER PEENEY
M.R.C.S.

Dr. A. L. P. Peeney, director of the clinical pathological service of the Queen Elizabeth and General Hospitals, Birmingham, died in the Queen Elizabeth Hospital on June 10 at the age of 50.

He was a son of the late John Peeney of Blackpool, and he studied medicine at Manchester University, qualifying in 1928. After holding appointments as house-physician at the Manchester Royal Infirmary and the Brompton Hospital, London, he became a member of the staff of the Royal Infirmary laboratory, and later of the public-health laboratory, in Manchester. In 1936 he was appointed clinical pathologist to the Queen's Hospital, Birmingham. Two years later, when the Queen's ceased to be a general hospital, his laboratories were transferred to the new Queen Elizabeth Hospital, where he remained in charge of pathology and hæmatology until his death. In 1946 he was given supervision also of the corresponding laboratories at the General Hospital, and was appointed an honorary lecturer in his subject at Birmingham University.

Shortage of staff and the steady increase in routine work gave him little time during the earlier years for research, but when these burdens were eased he made valuable contributions to his special subject, notably on the action of the antibiotics and the blood picture in the sprue syndrome. His descriptions of this blood picture are some of the earliest and most accurate that have been given. But the bare outline of his career and the short list of his publications go little way towards accounting for the influence and esteem which Peeney enjoyed in his hospitals and outside them. H. M. S., a member of his staff, writes: "Peeney's papers bear only a token relation to his knowledge, acuteness, and industry. He did not confine his interests to one type of disease, leaving the rest to his juniors and to laboratory routine, and for all cases he set the most exacting standards of investigation. He saw patients himself; he learnt every detail about them; he considered their problems with an anxious care which was often prolonged far into the night. This diligence and his natural shrewdness gave him an almost divinatory power of diagnosis far beyond his own field, and he seemed to be consulted by everyone about everything. In later years the unceasing stream of doctors seeking for his help took up the greater part of his day, but it is safe to say not one of them ever received the impression that Dr. Peeney was sparing his time with reluctance. Another great host of visitors was his patients. Among them, his warm personal interest, his kindness, and his courtesy commanded extraordinary respect and affection. Those who came up regularly for routine examinations still wished always to see Dr. Peeney, if only for a moment, and were inclined to go away dissatisfied if for once they did not succeed. His attitude of universal kindness was not unallied to an amused penetration into the characters of others. His staff can affirm that his tolerance of their faults was due to charity and not to blindness. Nor was his devotion to his work due to narrowness of interests. He had a full appreciation of all the good things of life. Of sport, particularly cricket, he was a keen follower, and his knowledge of its annals appeared to have no limits."

T. L. H. looked upon Peeney's department as the pivot on which the medical activities of the hospital turned; "and the man measured up to the stature of his work. Humility, charity, wisdom, and humour were his in full measure and he held malice towards none. Nothing was too much trouble, and even when beset with the many cares of his office he was always available in his laboratory or in the wards for consultation. The reports from his department were models of lucidity, and when difficulties arose they were invariably followed by Peeney himself in an attempt to clarify an obscure problem—and I recall with gratitude and pleasure many fruitful conversations over morning coffee. When the history of the early years of the Queen Elizabeth Hospital comes to be written the name of Angelo Peeney will hold an honoured place. Meanwhile the hospital mourns the

loss of a devoted servant, and his colleagues that of a lovable man. His memory will remain unforgettable and unforgettably."

Dr. Peeney is survived by his wife and a son.

DOUGLAS NOEL HARDCASTLE
M.R.C.S., D.P.M.

Dr. Noel Hardcastle, physician to the London Clinic of Psycho-Analysis, died on May 17 at the age of 62.

He was born in Brighton, the son of S. B. Hardcastle, and he studied medicine at St. Mary's Hospital, London, qualifying in 1915. He joined the R.A.M.C. almost at once and the following year went to France with the 60th London division. From 1920 to 1921 he served as a neurologist in charge of "shell-shock" wards at Ministry of Pensions hospitals in Edinburgh and Manchester.

After his return to civilian practice he took the D.P.M. in 1922 and was appointed to clinical assistantships at Bethlem Royal Hospital and in the psychiatric department at St. Mary's Hospital. He also continued to act as a specialist for the Ministry of Pensions at their London neurological clinic and to serve on their boards. During these years he served for a time on the staff of the Tavistock Clinic. In 1927 he was appointed to the staff of Moorcroft House under Dr. G. W. B. James, but in 1929 he gave up this post to spend three years of postgraduate study in the United States at child-guidance clinics in Philadelphia and Los Angeles. After his return to this country in 1932 he gave most of his time to this growing specialty. His work as the founder and director of the Fulham clinic quickly won recognition, and when child guidance was started by the Herts County Council, under the directorship of Dr. W. J. T. Kimber in 1934, Hardcastle was appointed psychiatrist to take clinical charge of the Hill End Hospital nerve clinic at St. Albans. He established the child-guidance service in Hertfordshire but resigned in 1938 because of ill health.

During the second world war he served as a psychiatrist with the Emergency Medical Service, first at Haymeads Emergency Hospital at Bishop's Stortford and later at Wharncliffe neurosis centre in Sheffield. Since 1943 he had been in consultant practice at Bishop's Stortford; he was also a physician on the staff of the London Clinic of Psycho-Analysis.

W. H. writes: "Dr. Noel Hardcastle was a keen thinker and observer of everything relating to the development and conflicts of children, and as the years went by he felt more and more the need to look for what was not on the surface. Uncompromising as he was, he underwent psycho-analytic training shortly before the second world war, and despite his age he insisted on seeing it through. In these last years, by combining work as a psychiatrist and psycho-analyst in a small provincial town with the pleasures of family life, he had found a solution for which other colleagues, perhaps with greater professional rewards, may silently envy him."

Dr. Hardcastle married Miss Kitty Duguid, who survives him with their three children.

SERGEI YUDIN
Hon. F.R.C.S.

Professor Yudin, chief surgeon of the Sklifosovski Hospital for Traumatic Diseases in Moscow and director of the surgical clinic of the Moscow Postgraduate Medical School, died on June 14 at the age of 64. He received the honorary fellowship of the English College in 1943.

Before the war Professor Yudin was chiefly known in this country for his use of stored cadaver blood for transfusion. As the central hospital for emergency surgery in Moscow the Sklifosovski Institute received many patients in urgent need of transfusion, while many severely injured people died in its receiving-rooms. Convenience may thus have led Yudin to use, and later to store, cadaver blood for the copious transfusions which he advocated, but he also believed that it had certain advantages over blood from a living donor—notably that it did not need the addition of an anticoagulant. A not unnatural repugnance had to be overcome, but in 1937 he was able to describe in our columns¹ an organisa-

1. *Lancet*, 1937, ii, 361

tion which he had built up over ten years, and to record that in over 1000 cases transfusions had been successfully given.

Yudin was also well known as a resourceful abdominal surgeon—he numbered his gastrectomies by the thousand. But during the war he turned his attention to the treatment of compound fractures. As his work on blood-transfusion showed, he believed in examining an urgent problem afresh, and the technique he advocated for these war injuries was different from the practice of most Western surgeons. He did not limit his intervention to casualties reaching operation within six to twelve hours, and he excised all necrotic tissues, making a large hole into the limb, and keeping it wide open by suturing the skin to the deep fascia not only in the primary wound but in any counter-opening that might be needed to secure free drainage.

When a British surgical mission visited Russia in 1943² they were struck by the vast scale on which surgery is done in the U.S.S.R., and one of the occasions of their wonder was to find their newly elected honorary fellow doing three operations in one day for the replacement of permanently obstructed oesophagus by jejunum, working with an astonishing rapidity and ease of technique.

Sir JAMES SPENCE

FEW men have the qualities of heart and mind required of a great teacher, but Sir James Spence possessed them in abundant measure. It was inevitable that young men were attracted to work with him, for he was a master of his subject, and, possessing a sensitive human philosophy of life, he liked helping and stimulating young men. From many parts of the United Kingdom and British Commonwealth of Nations men sought training with him, and as an Australian I had the honour and privilege of serving as a member of his team. My association with him developed into a warm friendship over the years, for it was characteristic of him to maintain an interest and help those who had worked with him.

In addition to his outstanding ability as a teacher James Spence made two great contributions to paediatrics. The first was his work on the care of children in hospital, the second in the field of clinical science. His wide knowledge of medicine and society, together with a humanitarian philosophy, were responsible for his revolt against the common and often rather inhuman practice of segregation of infant and child from its mother both in obstetric and children's hospitals. The principles of his practice of mother-child care in hospitals have now been widely accepted, and have done much to improve the care of the infant and child while in hospital and to abolish parental and child anxiety. In the field of clinical science Spence adopted the study of the whole individual and his environment. He maintained that this approach had been largely neglected and that there was much to learn, especially in children's illness. His departmental study of the illnesses and environment of a thousand families is an outstanding model and contribution towards understanding common family problems and illnesses.

He built his house well, for those young men whom he inspired and taught will carry on his work.

Melbourne, Australia.

H. W.

Dr. A. O. F. ROSS

E. E. P. writes: "A. O. F. Ross was not only one of the most distinguished venereologists of the day, but a man with an exceptionally broad background of knowledge. His enthusiasm and burning zeal were contagious and he shone as a teacher. He had unflinching sympathy and understanding, and generations of seafarers have reason to be grateful for his care and attention. He was a great doctor and a delightful host, and his great sense of humour made him a most amusing correspondent. He endeared himself to all; our hearts are heavy at his going."

2. *Ibid.*, 1943, II, 198.

Births, Marriages, and Deaths

BIRTHS

MANN.—On June 5, at Brighton, to Joy, wife of Dr. Trevor P. Mann—a third³son.

Diary of the Week

JUNE 20 TO 26

Monday, 21st

UNIVERSITY OF LONDON

5 P.M. (University College Hospital Medical School, University Street, W.C.1.) Prof. B. T. Mayes (Sydney): Postpartum Haemorrhage.

POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.12
4 P.M. Dr. Brian Ackner: Psychiatric Problems during Pregnancy and the Puerperium.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY
2 P.M. (Hammersmith Hospital, Ducane Road, W.12.) Prof. J. Louw (Cape Town): Pelvic Inflammation.

Tuesday, 22nd

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2

3.45 P.M. Prof. R. J. Last: Pectoral Girdle. (Arnott demonstration.)

Wednesday, 23rd

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1

5 P.M. Section of Endocrinology. Dr. G. W. Thorn (U.S.A.): Diagnosis and Treatment of Disturbance in Adrenal Cortical Function.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2

5.30 P.M. Dr. H. Haber: Acantholysis.

Thursday, 24th

UNIVERSITY OF OXFORD

8.30 P.M. (Nuffield Orthopaedic Centre, Wingfield-Morris Orthopaedic Hospital.) Prof. C. G. Rob: Present Status of Blood-vessel Grafting.

HONYMAN GILLESPIE LECTURE

5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Mr. D. L. Savill: Ankylosing Spondylitis.

Friday, 25th

POSTGRADUATE MEDICAL SCHOOL OF LONDON

2 P.M. Mr. T. McW. Millar: Surgical Experiences in Treatment of Obstructive Jaundice.

4 P.M. Dr. E. G. L. Bywaters: Collagen Diseases.

ROYAL SOCIETY OF MEDICINE

8.15 P.M. Section of Obstetrics and Gynaecology. Professor Mayes: Caesarean Section and Management of Subsequent Pregnancy and Labour.

INSTITUTE OF CARDIOLOGY

5 P.M. (1, Wimpole Street, W.1.) Dr. Graham Hayward: Pulmonary Oedema. (St. Cyres lecture.)

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY, 330, Gray's Inn Road, W.C.1

3.30 P.M. Mr. K. G. Rotter: Otitis Media in Children and Infants.

Appointments

BYRNE, UNA B., M.B. Belf., D.A.: anaesthetist, Fermanagh H.M.O.
DOWNING, D. M., M.B. Belf., D.A.: anaesthetist, North Antrim group of hospitals.

FLOOD, J. J., M.B. N.U.I., D.P.M.: senior asst. R.M.O., The Priory, Roehampton, S.W.15.

* HEPPLESTON, J. D., M.B. Manc., DIP. PATH.: consultant pathologist, South Cheshire Hospital centre.

JUSTICE, J. J., M.B., B.S.O. Glasg., D.P.M.: consultant psychiatrist and medical superintendent, St. Mary's Hospital, Stannington.

LAURIE, ALEXANDER, M.B. Glasg., D.P.H.: asst. county M.O.E., Derbyshire, and M.O.H., borough of Ilkeston and urban districts of Alfreton and Ripley.

RAMSBY, CHRISTINE M., M.B. Lond., D.A.: anaesthetist, Royal Cancer Hospital, London.

SIDDLE, J. L., M.B. Durh., D.P.H.: asst. county M.O., Durham (No. 4 area), M.O.H., urban and rural districts of Chester-le-Street.

Appointed Factory Doctors:

CADENHEAD, R. McN., M.B. Aberd.: Lerwick, Shetland.

KILVERT, E. E. K., M.B. Birm.: Clevedon, Somerset.

ROWNTREE, J. K., M.R.C.S.: Grantham, Lincoln.

The Bethlem Royal Hospital and the Maudsley Hospital:

HOBSON, R. F., B.A., M.D. Camb., D.P.M.: physician.

HOFFER, WILLI, M.D., PH.D. Vienna, L.R.C.P.E.: physician.

REES, W. L. L., M.D., B.S.O. Wales, M.R.C.P., D.P.M.: physician.

South-Western Regional Hospital Board:

AZAM, M. A., M.B. Punjab, F.R.C.S.E.: surgical registrar, South Devon and East Cornwall Hospital, Plymouth.

BALMFORTH, G. V., M.B. Lond., D.OBST.: medical registrar, Gloucestershire Royal Hospital, Glos.

COLE, PAULINE, M.B. Lond., D.C.H.: paediatric registrar, South Devon and East Cornwall Hospital, Plymouth.

DUTTON, J. E. M., M.B. Durh., F.R.C.S.: senior registrar, department of neurological surgery, Frenchay Hospital, Bristol.

GERRARD, JEAN O., M.B. St. And.: anaesthetic registrar, Bath group of hospitals.

HOY, C. H. A., M.B. Lond.: surgical registrar, Torquay and Newton Abbot hospitals.

Welsh Regional Hospital Board:

CORRADO, H. A., M.D. Malta: asst. chest physician (S.H.M.O.), Caernarvon and Anglesey H.M.O.

COSGROVE, P. C., M.B. Dubl., F.R.C.P.I., D.T.M. & H.: asst. chest physician (S.H.M.O.), Swansea.

SEAL, R. M. E., M.B. Wales, M.R.C.P.: consultant pathologist, Sully Hospital.

* Amended Notice.

Notes and News

AN APPEAL FOR THE RHEUMATIC

THE British Rheumatic Association has prepared a five-year plan including the setting up of special hostels, the promotion of medico-industrial reablement, village and home treatment, and measures to help the sufferer to help himself. To get this plan going an appeal is being made for £75,000 in the first year and £150,000 in subsequent years. At a luncheon held in London on June 10 Mr. Tom Williams, who presided, said that there were so many sufferers from rheumatism that the disease was often taken for granted; but the country could not afford to take it for granted any longer. Lord Horder, as "the father of the Empire Rheumatism Council," said that the council had primarily taken on the function of research, but at the same time had tried to make people understand how widespread and painful and costly the disease was. Ten years ago, in "A Plan for National Action," he had hammered on the doors of the Ministry of Health; and these had opened a little way—only alas to shut again. He hoped that the British Rheumatic Association would (1) do something to make early diagnosis easier, and (2) do something for patients after they had been treated in hospital. Here they would be undertaking work that the Empire Rheumatism Council could not undertake. And he hoped that they would mobilise public opinion, which could be done only by voluntary effort. When public opinion was mobilised, the official doors would open again.

Sir Walter Puckey explained that the association's scheme would be of direct value to industry. Rheumatism stood very high on the list of causes of absenteeism and loss of production. It was estimated that the disease caused the loss of some three million working weeks every year, and in terms of sickness benefit, medical care, and production loss the cost was put as high as £250 million a year—all this apart from the human suffering. As chairman of the Pioneer Hostel established at Bracken Hill House, Northwood, by B.R.A. Homes Ltd., of which he is chairman, Sir Walter expressed the hope that many other hostels of the same kind would be set up. Dr. Francis Bach said that rheumatism was not taken seriously enough in the early stages either by the sufferer, by the manager, or by the doctor. Also there should be more understanding of the importance of the relation between the man, his employer, and his work. Four stages of disability could be recognised: some patients regained full working capacity; a second group, though handicapped, could also carry on. A third group, however, required sheltered conditions and these ought to be provided. Many people, though called cripples, still could fill an important place in industry: if the kitchen does not suit one's wife, one does not change one's wife but modifies the kitchen—and similarly industrialists should modify their industrial processes. Work could be provided, too, for the home-bound. All this required careful planning; and at present, though the majority of rheumatism patients were fit to go back to work of some kind, it was extremely hard to get them replaced in industry.

The association's address is 11, Beaumont Street, W.1.

WELFARE FOODS

WHEN the local offices of the Ministry of Food close at the end of June, welfare foods—liquid milk, National dried milk, cod-liver oil, orange juice, vitamin tablets—will still be available for expectant mothers and young children, but the following changes will be made in the system:

Distribution.—From June 28 the foods themselves (except liquid milk) will be distributed by the local health authority at welfare clinics or other convenient centres. Liquid milk will continue to be distributed by dairymen.

Entitlement Documents.—Until the end of October, when a new system will start, existing ration books will continue to be used as proof of entitlement for expectant mothers, babies, and young children. These books should, therefore, be preserved carefully when food rationing ends in July. New applications for entitlement documents should be made to the local office of the Ministry of Pensions and National Insurance or, in some places, the Ministry of Labour and National Service.

SYMPOSIUM ON TUBERCULOSIS

THE latest issue of the *British Medical Bulletin*¹ contains a symposium on tuberculosis covering a large field stretching from laboratory research to the organisation of chest clinics. The quality of the articles varies widely. Some are outstanding, especially those on vaccination with the vole bacillus, the relationship between the host cell and the parasite, the action of cortisone and certain surface-active agents on

the tuberculous animal, and the detection of pulmonary tuberculosis in a community. The article on drug resistance may possibly confuse but will certainly stimulate the reader; and the importance of this subject to the clinician is admirably discussed by Dr. J. G. Scadding, the scientific editor. It is a pity that a few contributors seem to have forgotten that the *Bulletin* is intended primarily for foreign readers. A didactic style and criticism of the health and social services in this country are out of place in it.

SLEEP HABITS OF SCHOOL-CHILDREN

WE do not know how many hours of sleep any person needs, or (which is a different thing) how many he could use with advantage, given the opportunity. The need, in any case, varies from person to person, and in the same person over a lifetime.

Dr. G. P. McLauchlan¹ has made a small study of the sleep habits of children, aged 10½–11½, attending county primary schools in Guildford. All the children were examined physically and "no child with any defect likely to interfere with his wellbeing was included in the survey." The sleep habits of the 250 accepted for study were established by questioning them and their mothers. Their bedtimes varied widely, one of them going to bed at 6.30 P.M. and three at 10 P.M.; the largest number, however, went to bed at 8 o'clock. Most of them awoke or were awakened between 7 and 8 A.M. though one boy regularly awakened at 5. But going to bed is one thing and going to sleep is another; and McLauchlan took the precaution of finding out how long they stayed awake after getting there. An estimate based on the answers of the mothers and children suggests that one child was having as little as 7½ hours' sleep while three were getting as much as 12½ hours. The largest number got 11 hours, and some five-sixths of the total were having 10–11½ hours.

Sleep, however, varies in quality as well as quantity; and he quotes the work of Davis et al.², who distinguished, by electro-encephalography, five depths of sleep, merging into one another: (1) a stage of dropping off to sleep when one is neither asleep nor awake; (2) a stage of light sleep; (3) a deeper stage in which one can yet be easily disturbed; (4) sound sleep, in which the patient is not easily disturbed; and (5) really deep sleep. The depth of sleep varies in the course of the night, and in children the variation follows a fairly definite pattern. Depth of sleep increases rapidly from the moment the child falls asleep, and reaches a maximum by about the end of the 1st hour. Sleep then becomes progressively lighter until about the 6th hour, after which it again deepens, to reach a second period of great depth at the 8th or 9th hour. After that it becomes lighter again until the child wakes, or dozes until called. McLauchlan draws the conclusion, which may or may not be justified, that if a child is hard to waken in the morning he has not completed his sleep cycle, and so has not had as much sleep as he needs. Of his 250 children, 184 (three-quarters) awakened of their own accord, 53 awakened easily on being called, and 13 were difficult to waken.

He noted, too, that 43 of the children had a poor appetite for breakfast, a symptom which is also thought to be associated with a sleep deficiency; and indeed 7 of the 43 were among those difficult to waken. There were thus 49 children, who, judged by these standards, might be going short of sleep. But—unless their requirements were much above the average—the deficiency for most of them was not in quantity; for four-fifths of them were in bed by 8.30 and all but 5 were getting 10–12 hours' sleep. Some of them took longer to go to sleep than the other children studied, only slightly over half of them being asleep 30 minutes after going to bed, as against four-fifths of the rest. Reading in bed cannot be blamed, for only 9 of them enjoyed this privilege. Neither sharing a room nor sharing a bed seemed to interfere much with their sleep, and in any case more than two-thirds of them had a bed to themselves. Presumably their sleep deficiency was therefore a matter of quality rather than quantity; but it is hard to be sure from this study that these 49 children really were suffering from a lack of sleep. If they were, it had evidently not affected their health seriously, or they would not have been included in the survey. Their inability to waken easily and their lack of appetite for breakfast are interesting symptoms, certainly, but they are surely susceptible of other explanations besides a lack of sleep.

SPECIAL DIETS

THE Hospital Catering Advisory Service of King Edward's Hospital Fund for London has issued a useful booklet for the guidance of catering officers, kitchen superintendents, and housekeeping and nursing sisters at smaller hospitals where there is no trained dietitian.¹ The essentials of a balanced diet are explained, and, on the basis of this, various special diets are described: for diabetes; for reducing weight; gastric diets; bland low-residue diets; diet for occult-blood test; high-protein and low-protein diet; low-fat diet; salt-free diet; and gluten-free diet. A specimen kitchen sheet is given, and there are recipes for gastric diets, for saucers for fat-free diets, and for using gluten-free flour.

University of London

Dr. C. B. B. Downman, senior lecturer at St. Thomas's Hospital Medical School, has been appointed to the readership in physiology at the Royal Free Hospital School of Medicine.

Among those on whom the university will confer honorary degrees to celebrate foundation day on Nov. 26 is Sir Rudolph Peters, F.R.S., who will receive the degree of D.Sc.

University of Durham

Mr. D. J. Tibbs, first assistant in the department of surgery, has been appointed reader in surgery in the Newcastle division.

Royal College of Surgeons of England

The directors-general of the medical services of the Armed Forces attended a meeting of the council held on June 10, when the following medals were presented:

The Sir Gilbert Blane medal to Surgeon Commander J. L. S. Coulter; the Mitchiner medal to Lieut.-Colonel H. D. Chalke; and the Lady Cade medal to Squadron-Leader R. R. L. Fryer.

Mr. R. S. Handley (Middlesex Hospital) was admitted to the court of examiners, and Mr. D. M. E. Thomas (Sully, Glam) and Mrs. Dorothy Campbell (Coventry) were admitted to the fellowship.

The following were co-opted to the council for the year 1954-55 representing various branches of practice:

Dr. O. C. Carter (general practice), Prof. A. M. Claye (gynaecology and obstetrics), Mr. Myles L. Formby (otolaryngology), Dr. Bernard Johnson (anaesthetics), Mr. A. B. Nutt (ophthalmology), Dr. E. Rohan Williams (radiology). Prof. F. C. Wilkinson was invited to act as the representative of dental surgery.

The following examiners were appointed for the ensuing year:

Fellowship.—Ophthalmology: E. A. Blake Pritchard. Anatomy: D. N. Matthews, Mary F. Lucas Keene, Lambert C. Rogers, R. J. Last. Applied Physiology and Pathology: Geoffrey Hadfield, Albert Hemingway, J. L. D'Silva, H. A. Magnus.

Diploma of L.R.C.P., M.R.C.S.—Elementary Biology: Alan Fisk, G. E. H. Foxon. Anatomy: Thomas Nicol, E. W. T. Morris, A. J. Heriot. Physiology: C. C. N. Vass, Esther M. Killick. Midwifery: R. G. Maliphant, W. R. Winterton, H. H. Fouracre Barns, Ian Donald. Pathology: L. E. C. Norbury, Joseph Bamforth, A. C. Cunliffe, V. C. Pennell.

Diplomas of fellowship were granted to the following:

F. L. Davies, M. J. May, H. F. McG. Bassett, A. L. T. Easton, N. C. Rees, *M. J. Gilkes, W. J. Gall, F. E. Weale, A. L. Levene, I. L. Macfarlane, M. A. Brennan, W. F. W. Southwood, A. A. Eloy, Gerald Keen, O. L. Thomas, †A. G. Ackerley, Pamela M. Moody, F. H. Haine, Daya Shankar Kaicker, Anand Narain Razdan, †D. R. Scorgie, A. S. Dawson, Joseph Hirtenstein, †J. S. Martin, Kamel Mohamed Said, Michael Salvaris, Philip Goldstein, G. N. Perera, E. A. M. Ryan, *T. A. S. Boyd, P. F. Early, Catherine N. McRobert, Chimanbhai Jiwabhai Patel, Pesi Behramsha Bharucha, J. L. Edmondson, P. D. Hill, N. H. Birch, Ben-Ami Ellenberg, John Kirk, Chimanbhai Chaturbhai Patel, Nader Mohamed Souleim, Tarun Kanti Banerjee, *J. D. Brogan, J. R. Dickson, Michael Kugler, M. E. Lake, T. D. H. Perera, †B. H. Pickard, Khalid Abdul Azize Qasab, Piyasiri Rathnapala Walpita, J. A. M. White, Mohamed Yassin Ahmed Alyan, I. M. Cran, Ahmed Refaat El Mazny, Colm Galvin, J. G. Hamilton, †Akkinepalli Badri Narayan, Rao, J. S. Roarty, †H. W. H. Sheppard, H. F. R. Story, †T. P. Cannon, Sukumar Das, M. J. Gallagher, J. E. Howson, †J. F. Lee, Alexander McCallister, Tassaduk Hussain Moghul, Bernard Murphy, J. P. O'Neill, †P. B. O'Neill, D. N. Robinson, E. F. Soothill, R. T. Todd, W. F. Walker, Kadribuksh Yar Mohammed Ansari, R. A. Bailey, S. C. Baker, A. J. Davies, J. K. Francis, F. C. Hoyte, W. J. Metcalfe, Charles Miller, L. J. Optit, N. H. Porter, †Noel Roydhouse, Hassouna Mahmoud Saba, L. A. Wells, T. G. Lorentz, Maqbool Ahmad, Krishna Kant Bhatnagar, J. H. Kettle, Sarinder Man Singh.

* In ophthalmology. † In otolaryngology.

The fellowship of the faculty of anaesthetists was granted to B. H. Smith, and a diploma of membership of the college to H. N. Baylis.

1. Memorandum on Special Diets. 1954. Obtainable from King Edward's Hospital Fund for London, 10, Old Jewry, London, E.C.2. Pp. 36. 1s. post-free.

Royal College of Physicians of London

Dr. E. B. Verney, F.R.S., will deliver the Bertram Louis Abrahams lecture on Thursday, July 8, at 5 p.m., at the college, Pall Mall East, S.W.1. He is to speak on Renal Excretion of Water and Salt.

Royal College of Surgeons in Ireland

At a meeting of the college on June 7, the following officers were elected:

President, Ian Fraser; vice-president, A. B. Clery; other members of council, J. F. L. Keegan, R. A. Stoney, Henry Stokes, J. F. Devane, William Pearson, A. A. McConnell, T. O. Graham, William Doolin, Frederick Gill, T. G. Wilson, M. P. Burke, C. H. G. Macafee, R. R. Woods, S. F. Heatley, J. H. Coolican, T. A. Bouchier-Hayes, N. A. Kinnear, E. W. L. Thompson, J. M. McA. Curtin.

Royal College of Physicians of Ireland

At a meeting of the college held on June 4, with Dr. Edward Freeman, the president, in the chair, the following were admitted to the fellowship:

Alan Proctor Grant, Rex St. John Lyburn (in absentia).

The following were admitted to the membership:

H. T. F. Barnville, Mary E. Bewley, F. R. Cunnihan, C. K. Heffernan, Ferdinand Hillman, M. J. Lalor, A. J. MacDonald, Hugo McVey, Samuel Miller, W. A. Norris, A. P. H. Randle, Charles Reid, D. S. Wilson.

Lady Tata Trust

The trustees of this fund announce that they have made the following awards for research on leukaemia and allied diseases, in the year beginning next October:

Grants for research expenses.—Dr. Astrid Fagraeus and Dr. Bo Thorell (Stockholm); Dr. Jo Nordmann (Paris); Dr. Arunachala Sreenivasan (Bombay).

Senior research fellowship.—Dr. Jørgen Kleier (Copenhagen). *Scholarships.*—Dr. Ragna Rask-Nielsen (Copenhagen); Dr. Roger Robiniaux (Paris); Dr. Flemming Kissmeyer-Nielsen (Aarhus, Denmark); Dr. N. A. Stenderup (Aarhus, Denmark); Dr. Jørgen Ringsted (Copenhagen); Dr. Jørgen Rygaard (Copenhagen).

Part-time scholarship and grant for research expenses.—Dr. Maxime Selgmann (Paris).

A special scholarship awarded to Dr. Gavino Negroni (Italy), for work at the Imperial Cancer Research Fund Laboratories, will continue until April 30, 1955.

Mackenzie Industrial Health Lecture

Dr. W. M. Goldblatt will give the Mackenzie lecture on Tuesday, July 13, at 2.30 p.m. in the Library Theatre, Manchester. He will speak on Research in Industrial Health in the Chemical Industry.

North of England Society of Anaesthetists

On May 21 Dr. E. J. Millar, the president, presented the registrar's prize to Dr. F. Sorrell for his essay on bronchospasm. Dr. M. H. Armstrong Davison was elected president for the coming session, and Dr. E. I. Tate was re-elected hon. secretary.

Northern Ireland Health Services

Sir George Henderson, Mr. J. V. S. Mills, and Mr. H. G. Tanner (chairman) have been appointed to advise minister of health and local government on the health services in Northern Ireland. Dr. G. C. Kelly and Mr. N. Dugdale will act as joint secretaries to the advisers.

Wellcome Research Laboratories

Colonel H. W. Mulligan has been appointed head of the biological division of these laboratories, in succession to Dr. J. W. Trevan, F.R.S., who retired last year.

After graduating M.B. from the University of Aberdeen in 1923, Colonel Mulligan joined the Indian Medical Service. He was posted to its medical research department in 1928 and he remained in this branch, except for three years on active service during the war, ultimately becoming consultant malarialogist, Persia and Iraq Command. Among the appointments he held in India were those of director of the Pasteur Institute, Coonoor, and later of the Central Research Institute, Kasauli, where he had earlier been in charge of the serum and vaccine department. When the I.M.S. was disbanded in 1947 he went to West Africa to set up the African Institute for Trypanosomiasis Research. Colonel Mulligan is the West African representative on the Scientific Council for Africa, and a member of the International Scientific Committee for Trypanosomiasis Research and of the World Health Organisation expert panel on parasitic diseases. During the last three years he has shared in planning the West African Council for Medical Research, which was established a few months ago.

CORRIGENDUM.—The late Prof. J. B. Buxton, whose death we recorded last week, was president of the Royal College of Veterinary Surgeons in 1932-33, and in 1936 he became principal of the Royal Veterinary College.

REMARKS ON THE
ÆTIOLOGY OF BRONCHOGENIC
CARCINOMA *

EVARTS A. GRAHAM

M.D. Rush, F.A.C.S., F.R.C.S.(Hon.)

BIXBY PROFESSOR EMERITUS OF SURGERY, WASHINGTON
UNIVERSITY

From the Department of Surgery, Washington University School
of Medicine and Barnes Hospital, St. Louis, Missouri

PROBABLY everyone here is aware of the claim that bronchogenic carcinoma is a much more common condition than it was thirty or thirty-five years ago. Although there are still a few who, like Smithers of the Brompton Hospital, are sceptical of this claim (Smithers 1953), the overwhelming majority of those who have studied the question are thoroughly convinced. There has been a striking increase in the incidence of the disease which cannot be explained by the greater longevity of people nowadays or by better diagnosis. Few realise, however, that the very remarkable increase is unique in the field of cancer. Probably never before in medical history has a cancer of a particular organ shown so rapid an increase. Other common cancers with which we are familiar are showing either no change or perhaps even a slight decline in incidence (fig. 1). Cancer of the respiratory system in the United States, and I believe in the United Kingdom, has now jumped to the leading position, superseding cancer of the stomach for first place.

One other generality that should be mentioned here is that the condition is much more frequent in men than in women. Various ratios are given in the literature. An average of them shows that bronchogenic carcinoma is about six times more frequent in males than in females.

* From the second Sir John Fraser lecture delivered at the University of Edinburgh on May 11, 1954.

Fig. 1—Death-rates for selected respiratory diseases and sites of cancer among white males, United States 1930-50. (Rates standardised for age on the 1940 population.) Showing the rapid rise in the curve of incidence of cancer of the respiratory system in comparison with the nearly straight lines of other common cancers. (Prepared by Dr. E. Cuyler Hammond, chief statistician of American Cancer Society, and reproduced with his permission.)

This fact in itself arouses curiosity because there is no reason whatever for assuming that there is any anatomical or physiological difference between the lungs of the two sexes.

If we accept these facts it behoves us to try to find an explanation for them. Immediately of course the idea occurs that the explanation of the very rapid increase in incidence must lie in something pertaining to our culture or habits in the last thirty-five years which differs from those of a previous time. At once the possibility of some factor connected with the motor-car comes to mind, since this is the motor age. In a study, however, of 857 cases of bronchogenic carcinoma by Wynder and myself (1951), with special reference to industrial exposures as possible ætiological factors, we found no significant increase of this cancer in garage men, automobile mechanics, chauffeurs, and oil-field workers. Certain other occupational exposures are known to be associated with a greater risk of developing lung cancer than the risk run by the general population. The most striking examples are the well-known studies made on the Schneeberg and Joachimsthal miners with incidences of 40% and 48% respectively of deaths from lung cancer in the two places. Lorenz (1944) has published an admirable review of this subject. Also, more recently, it has been found that workers in the chromate industry have a higher death-rate from pulmonary cancer than does the general population (Mancuso and Hueper 1951). These industrial exposures, however, could not possibly explain the large increase in the incidence of lung cancer, because so few people are involved. Also, despite the fact that small amounts of carcinogenic agents have been found in the atmospheric "smog" of some cities, as, for example, in Los Angeles by Kotin (1954), it would be difficult to explain the lower incidence of the disease in the women who inhale the same atmosphere as the men.

Relation to the Tobacco Habit

As long ago as 1912 Adler, of New York, who wrote the

first monograph on bronchogenic carcinoma, at a time when the condition was relatively rare, suggested that perhaps tobacco-smoking might be of some importance in the ætiology. Since that time the list of those who have made the same suggestion has become a long one. The difficulty, however, has been that in most instances only the suggestion was made and nothing was done to try to find out. What was needed was a statistical study on a sufficiently large number of patients to make the results significant.

In May, 1950, Wynder and I published such a study, based on 684 proven cases. Nearly all the patients were in the Barnes Hospital, St. Louis, but they came from many places in the Middle West and Southwest of the United States. They were interviewed about their

Fig. 2—The amount of cigarette-smoking in 605 male patients with proven bronchogenic carcinoma as compared with 780 males over 35 years of age without cancer of the lung (Wynder and Graham 1950).

The arbitrary classifications of smoking are as follows: Non-smokers (less than one cigarette per day for more than twenty years); light smokers (up to one-half pack per day for more than twenty years); moderately heavy (one-half to three-quarters of a pack); heavy smokers (three-quarters to a whole pack); excessive smokers (one to one-and-three-quarters packs); chain smokers (more than one-and-three-quarters packs).

smoking habits by one of three young women who used a standard questionnaire. In our study we found that of 605 men with bronchogenic carcinoma, other than adenocarcinoma, no less than 86.5% had smoked from about a pack to more than two packs of cigarettes a day for at least twenty years †; and among these men with the two common types of carcinoma (epidermoid and undifferentiated) only 1.3% were non-smokers. Of a control group of 780 men without lung cancer 54.7% had a similar history of heavy smoking of cigarettes, and 14.9% were non-smokers (fig. 2). We found also that no less than 72% of the men with lung cancer stated that they had smoked for from thirty to fifty years. Another important finding concerned the smoking habits of women. Although it is commonly stated that women smoke at least as much as men, if not more, the findings of our study of 552 women patients without lung cancer and above the age of 35 revealed the rather astonishing fact that 79.6% of them were non-smokers, as compared with only 14.9% of men in a similar control group (fig. 3). It is clear, therefore, that, at least in the United States, it is not true that women in general smoke as much as men. It is the young women and the girls who do the heavy cigarette-smoking, not the women of the cancer age. Moreover, the young women have not been smoking for the period of more than twenty years which seems to be necessary in order to develop a cancer of the lung.

In September of that year appeared in England the well-known statistical study of Doll and Hill (1950). Although it happened to be published a few months after ours it was begun about the same time and was carried on entirely independently of ours. It was based on about the same number of patients, who were interrogated in about the same manner as ours. Their results also closely resembled ours. For example, of 649 men with cancer of the lung only 0.3% were non-smokers. A high proportion of the patients with lung cancer were in the heavier-smoking categories. Doll and Hill conclude that their figures "suggest that, above the age of 45, the risk of developing the disease increases in simple proportion with the amount smoked, and that it may be approximately 50 times as great among

† A pack contains 20 cigarettes.

those who smoke 25 or more cigarettes a day as among non-smokers."

Actually, in addition to our own (Wynder and Graham 1950, 1951) and that of Doll and Hill (1950) ten different statistical studies have been reported (Breslow et al. 1954, Dungal 1950, Gsell 1951, Kouloumies 1953, Levin et al. 1950, McConnell et al. 1952, Mills and Porter 1950, Sadowaky et al. 1953, Schrek et al. 1950, Wynder and Cornfield 1953). Some are less significant than others because the numbers of cases were too small. Nevertheless, all the studies reported point in the same direction in showing a probable relation between excessive cigarette-smoking and the production of bronchogenic carcinoma. No study has failed to show a relation.

Carcinogens in Tobacco Smoke?

Although the statistical studies suggest very strongly that excessive cigarette-smoking plays an important part in the aetiology of lung cancer, it is obvious that experimental production of cancer with cigarette smoke would make the evidence stronger. The literature on this subject is long. It has been carefully reviewed in a recent article by Wynder, Croninger, and myself (1953). For the most part the results have been negative, though a total of seven epidermoid cancers of the skin have been reported as having been obtained in mice with products of cigarette smoke, out of many animals used. Most workers who have attempted to incite experimental cancer with tobacco products have used rabbits. Roffo (1939) reported the successful production of carcinoma in rabbit ears after painting them with a distillate of tobacco, but Sugiura failed in his attempt to reproduce Roffo's results. Also Flory (1941) succeeded in obtaining only "carcinomatoids" in rabbit ears after application of a tobacco distillate.

It seemed to us, after studying the literature, that the occurrence of cancer in the experimental animals was so rare that it offered little if any conclusive evidence beyond that produced by the statistical studies. Moreover, little was known or stated about the strains of mice used. This is a very important matter because, for the experiments to have value, a strain of mice must be used which is known not to develop spontaneous cancers of the skin. Accordingly we undertook an experimental study to determine whether we could produce cancer by

Fig. 3—This chart (Wynder and Graham 1950) refutes the common belief that women smoke as much as men, at least in the St. Louis area. The statistics were obtained by questioning 780 male and 552 female patients in the Barnes Hospital. None of the patients had a bronchial carcinoma and all were more than 35 years old.

painting the skin of mice of a suitable strain with tar collected from cigarette smoke. For our purpose we used mice belonging to the inbred strain known as CAF₁ which is free from spontaneous tumours of the skin. This strain has been developed in Dr. C. C. Little's laboratory at Bar Harbor, Maine.

We devised a machine with which we smoked 60 cigarettes at a time by means of a small motor. The smoke was drawn into flasks which were cooled with dry ice. The sudden cooling of the smoke resulted in the precipitation of the tar from the smoke. This tar was dissolved in acetone and the solution was painted on the skin of the mice. Thrice-weekly paintings of a solution of one part of tar to one part of acetone were used. The acetone proved to be an inert substance which failed to produce even any irritation of the skin of control mice which were painted with that substance alone.†

Of 81 tarred CAF₁ mice, 59% (26 females and 22 males) developed papillomas. Of these papillomas, 8.6% regressed. More important, however, was the fact that

Fig. 4—Carcinoma induced in mouse by painting with tobacco tar ($\times 50$).

of the 81 tarred mice 44.4% (or 36 mice) developed epidermoid cancer of the skin (figs. 4 and 5). In most instances there was only one cancer but in several cases there were two, and in one mouse actually three cancers appeared on the painted area. In view of the preponderance of incidence of lung cancer in the human male it is of interest that in the experimental animals 25 of the cancers occurred in females and 11 in males.

Several of the cancers produced in the mice have been successfully transplanted into other mice. In one example, successful transplantation was carried out for twenty generations.

One of the striking results of the experiments was the fact that the average time of appearance of a cancer was after seventy-one weeks of painting. This period of time represents a little more than one-half the average life-span of the mouse, which is ordinarily a little more than two years. The duration of painting required to produce a cancer in a mouse is thus equivalent to the approximate thirty to fifty years of smoking in the human required to produce a bronchogenic carcinoma; for that period is a little more than one-half the life-span of the human.

† For details of the experimental work the reader should consult our original article (Wynder, Graham, and Croninger 1953).

Fig. 5—Same lesion ($\times 200$).

These experimental results demonstrate that there is something in the smoke of cigarettes which is capable of producing carcinoma of the skin of mice.

Significance of the Findings.

What is the significance of the findings? We find that many thoughtful people believe that our experimental results bring to the statistical studies additional convincing evidence of an aetiological relation between excessive cigarette-smoking and bronchogenic carcinoma. There are others, however, who remain unconvinced. These "die-hards" state that so far no proof of the relation has been presented. One must grant that indeed no absolute proof has been offered. But what sort of proof is called for? To satisfy the most obdurate of the die-hards it would be necessary to take the following steps:

- (1) Secure some human volunteers willing to have a bronchus painted with cigarette tar, perhaps through a bronchial fistula.
- (2) The experiment must be carried on for at least twenty or twenty-five years.
- (3) The subjects must spend the whole period in air-conditioned quarters, never leaving them even for an hour or so, in order that there may be no contamination by a polluted atmosphere.
- (4) At the end of the twenty-five years they must submit to an operation or an autopsy to determine the result of the experiment.

I will say to those who wish to volunteer for such an experiment, "please form a queue to the right; no crowding please."

Perhaps the animal experiments might be somewhat more convincing if the cancers had been produced in the bronchi instead of in the skin; but there can be no doubt that we have demonstrated the presence of a carcinogenic factor in cigarette smoke. The technical experimental difficulties in the attempt to produce a cancer of the bronchus in a mouse are very great. Long-term inhalation experiments for the most part have been fatal because the mouse is relatively intolerant to nicotine. Indeed, after the cancers had ulcerated, we were compelled to use denicotinised tar in the painting of the animals because fatal amounts of nicotine were absorbed through the raw surface of the ulcer. If larger animals are used, in order to create bronchial fistulae more easily, the experiment must be carried on for a much longer time in view of the apparent rule that the contact with the tar must be for approximately one-half the life-span of the animal. Actually for a period of two and a half years we have been painting some bronchial fistulae in dogs, but we expect to have to continue the experiment for about three years longer.

Different Kinds of Carcinoma

One source of the disagreement among those who are interested in this subject is, it seems to me, the common opinion that bronchogenic carcinoma, or primary cancer of the lung, is a single entity. (The statisticians, who know little, if anything, about pathology, are especially likely to fall into that error.) Actually, there is much evidence that there are at least three distinct varieties of this disorder, differing from each other so much that they may be regarded as three distinct diseases, with different aetiological factors.

I fully realise that one should not place too great reliance on differences and classifications based on the morphological appearance and arrangement of cells. As a rule there is no great difficulty in distinguishing between a typical epidermoid (or squamous) carcinoma and an adenocarcinoma, but there are a good many cases in which there is very little differentiation. Usually in such examples it is possible to recognise a tendency towards the development of an epidermoid carcinoma, and we are therefore accustomed to speak of cancers showing such characteristics as undifferentiated epidermoid carcinomas.

We are inclined, then, to recognise as the three principal varieties of bronchogenic carcinoma (1) the epidermoid or squamous, with its subhead of undifferentiated carcinoma, (2) the adenocarcinoma, and (3) the so-called alveolar-cell carcinoma. The tumour which you British often designate as the oat-cell carcinoma is not regarded by us as a separate variety.

That which goes by the name of alveolar-cell carcinoma is rare in comparison with the other varieties, but from year to year more cases are recognised. It closely resembles the disease of sheep known as "jagziekte," and there is good reason to believe it is due to a virus.

In our experience by far the most common bronchial carcinoma is the epidermoid, with its variant the undifferentiated type. It constitutes more than 90% of the cases in our series. It is this variety which is apparently associated with excessive cigarette-smoking and it is found much more often in the male than in the female.

The typical adenocarcinoma has many characteristics, both clinical and pathological, which set it apart from the epidermoid cancer. Statistically it seems to have a much less close relation to smoking. For example, in our series, out of 39 men with adenocarcinoma no fewer than 4 (or 10%) were non-smokers, whereas among the other 605 men with bronchogenic carcinoma the proportion of non-smokers was only 1.3%. More striking is the fact that of 15 women with adenocarcinoma 13 were non-smokers. Another difference noted is that the very great preponderance of incidence of epidermoid carcinoma in the male sex does not hold to the same degree for the adenocarcinoma. Again, as shown by Olson (1935) and others, the primary carcinoma of the lung occurring in the younger age-groups is nearly always adenocarcinoma. Indeed Olson states that of 576 cases of lung cancer compiled from the literature by Brunn in 1926, 12% were in the age-group 20-29, and all of them were adenocarcinoma. All these characteristics seem, therefore, to suggest that the adenocarcinoma is a different entity from the epidermoid cancer. In 1938 Womack and I called attention to the malignant potentiality of the so-called bronchial adenoma. At first the idea was not generally accepted but now apparently there are few who doubt it. When this tumour does become malignant the arrangement of the cells is often of a pattern to suggest an adenocarcinoma. In some cases of adenocarcinoma, therefore, the cancer has probably originated in a so-called bronchial adenoma which has undergone malignant transformation.

Many of the die-hards who are unwilling to concede that there is any causal relation between cigarette-smoking

and cancer of the lung base their objection on the ground that they have known people to develop lung cancer who had never been smokers. If it is realised and admitted that different varieties of the condition are separate entities with different aetiologies it becomes easier to understand that, for example, a high percentage of non-smokers may be found among the group of adenocarcinomas but a low percentage in the group of epidermoid carcinomas. Again, of course, nobody would be foolish enough to state that cigarette-smoking is the only cause of bronchogenic carcinoma. As I have mentioned, the high incidence of lung cancer in the Schneeberg and Joachimsthal miners, as well as in workers in the chromate industry, suggests that some carcinogenic substance was inhaled by the workers in those industries. Moreover, for any malignant transformation to take place, there must be a reaction of the host's cells to the carcinogenic agent. After all, in our animal experiments with cigarette tars, only 44% of the mice developed carcinoma: the other 56% did not respond to the stimulus in the same way.

WHEN streptomycin was given alone in pulmonary tuberculosis, the bacilli became drug-resistant in a high proportion of patients from whom positive cultures were obtained after the third month of treatment. It was found that once the bacilli from a patient had become consistently streptomycin-resistant they usually remained so indefinitely. It was often pointed out that there was a danger that such a patient might infect others with his drug-resistant organisms. Harold (1951) has collected from published reports 9 cases in which tubercle bacilli isolated before treatment were found to be streptomycin-resistant. In most a source of infection could be identified. He added 2 further cases of his own, making 11 in all. Of these cases 6 were

pulmonary tuberculosis, 2 were tuberculous pleural effusions, 2 were tuberculous meningitis, and 1 was a primary tuberculous complex in the lung. In addition Debré et al. (1951) have reported 4 cases of tuberculous meningitis in which the bacilli were streptomycin-resistant before treatment was begun.

Similar dangers presumably exist when either *p*-aminosalicylic acid (P.A.S.) or isoniazid is given alone. The emergence of isoniazid-resistant bacilli in a high proportion of cases has been established by the Medical Research Council (1953a), but isoniazid has been used for a relatively short time, and we are not aware of any reports of the transmission of resistant organisms to new cases apart from 1 accidental laboratory infection (Borgen 1953). The emergence of P.A.S.-resistant bacilli when P.A.S. is given alone has received little attention in this country, but there is no doubt that it is a real danger. When tests for P.A.S. resistance have been made, resistant tubercle bacilli have been isolated in an important proportion of cases. Fresh evidence on this subject has recently been reported and the published cases have been reviewed by Turnbull et al. (1953). So far as we know, no case of infection by P.A.S.-resistant bacilli has previously been recorded.

Material and Methods

We report here cases from which tubercle bacilli resistant to streptomycin or to P.A.S. or to both were isolated but which had never received the drug to which their bacilli were resistant. Except when otherwise stated drug-sensitivity tests were made by the methods recommended by the Medical Research Council (1953b). The figures given for streptomycin and P.A.S. sensitivities are the ratio of the drug resistance of the test organism to that of the control strain H37Rv. The minimal inhibitory drug concentrations for each strain, in $\mu\text{g. per ml.}$, are given in parentheses where these are known, the test strain being the numerator in each case.

Findings

INFECTION WITH PRIMARILY STREPTOMYCIN-RESISTANT BACILLI

Case 1.—A man, aged 30, was admitted to Robroyston Hospital, Glasgow, in 1951 with bilateral pulmonary tuberculosis, which probably dated from 1947. Later he developed right sacro-iliac disease with a superficial abscess, which was aspirated on numerous occasions but provided no tubercle bacilli. Tubercle bacilli cultured from the sputum in May, 1952, had a streptomycin-resistance ratio of 8 (2/0.25 $\mu\text{g. per ml.}$) and a P.A.S.-resistance ratio of 2 (0.5/0.25 $\mu\text{g. per ml.}$) and were sensitive to 0.2 $\mu\text{g. per ml.}$ of isoniazid. There was no known source of infection. The patient was treated daily with streptomycin and isoniazid for three months, with moderate improvement. Cultures were negative until September, 1952 (after two months' treatment), when the sensitivities to all three drugs were unaltered. All further cultures were negative.

The history suggested that this patient had had pulmonary tuberculosis since 1947, though no radiograph was taken at that time. Streptomycin-resistant bacilli were exceedingly rare in 1947; hence this may have been a case of superinfection by streptomycin-resistant bacilli, the source of infection being unknown.

Case 2.—A girl, aged 17, was admitted to Aintree Hospital Liverpool, in April, 1952, with four months' history of cough. Radiography showed bilateral pulmonary tuberculosis. She had received streptomycin and P.A.S. for four days before admission. Culture of the sputum showed a streptomycin-resistance ratio of 128. Tests for P.A.S. resistance were not made. The patient's mother had had open pulmonary tuberculosis since 1950 and had been treated with P.A.S. alone for two months before the patient's admission; her bacilli were sensitive to streptomycin. A sister had had pulmonary tuberculosis since 1948 and had been treated both with streptomycin alone and with P.A.S. alone at different times; tubercle bacilli grown from her sputum had a streptomycin-

resistance ratio of 128. Two other sisters (twins) also had pulmonary tuberculosis, but their sputum was negative. The patient was treated with streptomycin 1 g. daily and P.A.S. 20 g. daily. Positive cultures of unaltered sensitivity were obtained one and two months after treatment began. There was moderate clinical and radiographic improvement during three months' chemotherapy but in the subsequent three months on rest in bed only she deteriorated slightly.

The patient was infected, probably by her sister, with tubercle bacilli moderately resistant to streptomycin.

Case 3.—A man, aged 26, was admitted to Aintree Hospital in April, 1952, with pulmonary tuberculosis, abnormal radiographic shadows having been present since 1947. A positive culture on admission gave a streptomycin-resistance ratio of 128 and a P.A.S.-resistance ratio of 0.5. There were two domestic contacts of the patient, neither of whom was said to have had streptomycin. The patient's wife had abdominal and pulmonary tuberculosis but had only received a month's streptomycin and P.A.S. when the patient was admitted. The patient was treated with streptomycin and P.A.S. daily for three months, with moderate clinical and radiographic improvement. Culture after the first month of treatment gave a streptomycin-resistance ratio of 128; no further positive cultures were obtained.

Since this patient was known to have had pulmonary tuberculosis in 1947 he had probably been subsequently superinfected from an unknown source with a streptomycin-resistant strain.

Case 4.—A man, aged 49, was admitted to the City Hospital, Edinburgh, in July, 1951, with chronic bilateral pulmonary tuberculosis, which had been present at least since March, 1947 (mass-radiography film). Drug sensitivities were first tested in April, 1952, when the streptomycin-resistance ratio was 8 (4/0.5 $\mu\text{g. per ml.}$) and P.A.S.-resistance ratio 16 (2/0.12 $\mu\text{g. per ml.}$); the bacilli were fully sensitive to isoniazid. The patient had been given P.A.S. alone for six months in 1949-50 but had never had streptomycin. His only son had been discovered in July, 1948, to have pulmonary tuberculosis and had died, without having received chemotherapy, in January, 1950. His wife was found to have extensive pulmonary tuberculosis in October, 1949. She received streptomycin and P.A.S. daily for forty-one days, after which P.A.S. was continued alone for five months. P.A.S. was then supplemented by streptomycin 1 g. twice weekly for a further nine months. She died four months later. Although no resistance tests were made, it seems very likely that, on the above régimes, her tubercle bacilli would have become resistant first to P.A.S. and later to streptomycin (Turnbull et al. 1953). Her husband nursed her throughout most of this illness. From April, 1952, before the sensitivity results were obtained, he was treated with streptomycin 1 g. daily and isoniazid 200 mg. daily. Twenty-five days after the start of this régime bacilli resistant to 0.2 $\mu\text{g. per ml.}$ of isoniazid and with a streptomycin-resistance ratio of 64 (8/0.125 $\mu\text{g. per ml.}$) were isolated; fifty-eight days after the start the bacilli were resistant to at least 50 $\mu\text{g. per ml.}$ of isoniazid. There was no clinical or radiographic response to therapy.

This patient was known to have had pulmonary tuberculosis at least since March, 1947, and was probably superinfected by his wife with streptomycin-resistant tubercle bacilli. Subsequent treatment with concurrent streptomycin and isoniazid did not prevent the emergence of isoniazid-resistant bacilli.

INFECTION WITH PRIMARILY P.A.S.-RESISTANT TUBERCLE BACILLI

Case 5.—A girl, aged 18, was admitted to Aintree Hospital in September, 1952, with bilateral pulmonary tuberculosis. She had no known domestic contacts; other patients lived in the vicinity, but none had had P.A.S. A sputum culture on admission gave a P.A.S.-resistance ratio of 64 (8/0.12 $\mu\text{g. per ml.}$). The patient was treated with P.A.S. and isoniazid daily but discharged herself before completing three months' treatment. A second culture, in December, 1952, after two months' chemotherapy gave a P.A.S.-resistance ratio of 8 (2/0.25 $\mu\text{g. per ml.}$). The culture on admission was resistant to 0.2 $\mu\text{g. per ml.}$ of isoniazid, which could be regarded as within normal limits of sensitivity; after two months the bacilli were

resistant to 1 µg. per ml., probably indicating a significant rise in resistance.

The patient was infected from an unknown source with a P.A.S.-resistant strain of tubercle bacilli. By the time this was established she had been treated with daily P.A.S. and isoniazid; after two months' treatment the organisms had become slightly isoniazid-resistant.

Case 6.—A woman, aged 33, was admitted to Southfield Hospital, Edinburgh, in May, 1952, with extensive tuberculosis of the left upper lobe. She had had a left pleural effusion a year previously. There was no known source of infection. A culture on admission gave a P.A.S.-resistance ratio greater than 256 (>32/0.12 µg. per ml.) but was sensitive to streptomycin. Before this was known the patient was treated with daily streptomycin and P.A.S. The last positive culture, after two months' treatment, was still sensitive to streptomycin, but the P.A.S.-resistance ratio was at least 16 (>2/0.12 µg. per ml.). The patient subsequently made excellent progress, and laryngeal swabs were still negative a year later.

The patient was primarily infected with a P.A.S.-resistant but streptomycin-sensitive strain of tubercle bacilli. No source of infection was known. Sputum conversion took place after two months' treatment with daily streptomycin and P.A.S.

Case 7.—A boy, aged 18, with congenital pulmonary stenosis, was known to have had pulmonary tuberculosis since 1946, but had never been given P.A.S. There was no known source of infection. He was admitted to Southfield Hospital in March, 1953, with bilateral fibrotic apical tuberculosis. Tubercle bacilli cultured on admission had a P.A.S.-resistance ratio of 64 (4/0.06 µg. per ml.) but were sensitive to streptomycin and isoniazid. Before this was known, the patient was treated with isoniazid 100 mg. and P.A.S. sodium 5 g., both given twice daily. After two months' treatment two cultures within four days gave P.A.S.-resistance ratios of 4 (1/0.25 µg. per ml.) and greater than 1000 (>64/0.06 µg. per ml.). Such fluctuations are not uncommon with P.A.S. resistance. The first of these cultures was resistant to 50 µg. per ml. of isoniazid on solid medium. Two months later two further cultures remained highly resistant to isoniazid. There was some initial clinical and radiographic improvement.

As tuberculosis was known to have been present since 1947, this patient had presumably been superinfected with P.A.S.-resistant tubercle bacilli. The combination of P.A.S. with isoniazid did not prevent the emergence of isoniazid resistance.

Case 8.—A boy, aged 15, was admitted to Southfield Hospital in May, 1952, with tuberculous meningitis. There was no known source of infection. He was treated with daily intrathecal and intramuscular streptomycin, and daily P.A.S. The positive cultures obtained from the cerebrospinal fluid on admission, and after two days' treatment, had died before P.A.S. sensitivity was tested; these cultures were sensitive to 3 µg. per ml. of streptomycin on solid medium. The first culture on which P.A.S. sensitivity could be tested was obtained five days after treatment had begun; three tests on this culture gave P.A.S.-resistance ratios of 8, 32, and 32. The presence of P.A.S.-resistant tubercle bacilli within five days of the start of treatment suggested that the organisms were almost certainly resistant before treatment was begun. Seven days after the start of treatment a culture gave P.A.S.-resistance ratios of 4, 32, and 32 in three tests, and streptomycin ratios of 1 and 2 (probably sensitive). The patient died after about four months' treatment. Cultures obtained post mortem were resistant to 5 µg. per ml. of streptomycin on solid medium though sensitive to 10 µg. per ml.

This patient was almost certainly infected with P.A.S.-resistant bacilli, which also became resistant to streptomycin while under treatment with streptomycin and P.A.S.

INFECTION WITH TUBERCLE BACILLI PRIMARILY RESISTANT TO STREPTOMYCIN AND P.A.S.

Case 9.—A woman, aged 36, was referred from an antenatal clinic in Edinburgh in July, 1953. Bilateral apical tuberculosis had been found on routine radiography. There was

no known source of infection. Tubercle bacilli obtained on culture of the sputum had a streptomycin-resistance ratio of 512 (128/0.25 µg. per ml.) and a P.A.S.-resistance ratio of 256 (16/0.06 µg. per ml.). She was treated with rest in bed, streptomycin, and P.A.S. for two months before the sensitivity results were known. There was some clinical improvement but no radiographic change even though the lesions were of an exudative type which would have been expected to respond to chemotherapy. No further positive culture was obtained.

This patient was apparently primarily infected with tubercle bacilli, highly resistant to both streptomycin and P.A.S. There was no known source of infection.

Discussion

In the light of present knowledge the proportion of patients in whom drug-resistant bacilli emerge, and who may pass these on to other people, should be small. Several of the present patients were probably infected when the dangers of giving P.A.S. alone were not generally appreciated, and when large numbers of patients were treated in this way. Others may have been infected by patients whose bacilli had become streptomycin-resistant before methods of preventing this were known. If present knowledge is sufficiently widely applied, such tragedies should become even rarer. We wish to emphasise once more the impropriety of giving one drug alone.

Our attention has recently been drawn to the possibility that at least some strains of bovine tubercle bacilli may be relatively insensitive to P.A.S. (Djang et al. 1952). The P.A.S.-resistant bacilli recorded here were not typed, because we had no reason to suspect bovine tuberculosis; but in future it would be wise to type any tubercle bacilli which appear to be primarily P.A.S.-resistant.

The controversy about the possibility and frequency of superinfection has continued for many years. Previously it could only be proved by superinfection by bovine or human infection, or vice versa. Drug resistance provides another label for the tubercle bacillus, and in 3 of the present cases (cases 3, 4, and 7) there is a strong suspicion that the patient was superinfected with drug-resistant bacilli. In a 4th case (case 1) superinfection may have taken place, but the evidence is more doubtful.

Summary

9 cases are recorded in which drug-resistant tubercle bacilli were obtained although the patient had received no previous chemotherapy with the relevant drug. In 4 of the patients the bacilli were primarily resistant to streptomycin, in 4 to P.A.S., and in 1 to both drugs.

3, and possibly 4, of the patients were known to have had tuberculosis before the relevant drug was in general use. Their original bacilli are therefore presumed to have been drug-sensitive, and it is thought that they had been superinfected with resistant bacilli.

We wish to thank Prof. A. W. Downie, Dr. Matthew Laidlaw, and Dr. A. T. Wallace, bacteriologists respectively at Liverpool, Glasgow, and Edinburgh, and Dr. D. A. Mitchison, of the Postgraduate Medical School of London, and Miss Sheila Stewart, of the department of tuberculosis and diseases of the respiratory system, University of Edinburgh, for making some of the tests for P.A.S. sensitivity; and Dr. Wallace Fox for helpful criticism. The Edinburgh cases were investigated in the course of research financed by the Royal Victoria Hospital Tuberculosis Trust.

ADDENDUM

Since this paper was written, 6 additional cases of infection with P.A.S.-resistant bacilli have been recorded in the Edinburgh Centre.

Arterial grafts have been stored in several different ways, notably by refrigeration in a nutrient medium (Gross et al. 1949) and in the frozen state (Eastcott and Hufnagel 1950). Of these two methods we have preferred frozen storage because it has worked better in practice (Rob and Eastcott 1953). The main disadvantage of "deep-freezing" for artery banking has been the need for maintaining at all times the low temperatures necessary to avoid physical and chemical changes in the grafts. Transportation in particular has been troublesome; special containers are needed, and detailed travelling arrangements have to be made.

An alternative method of preserving proteins is to dry them from the frozen state. This method is finding increasing application in the laboratory and in commerce; plasma, antibiotics, sera, and some food-stuffs can be stored readily and for a long time at room-temperature in vacuum containers after freeze-drying. Arteries the surgeon can carry in his instrument bag or post to other parts of the world with as much ease as a glass ampoule can be prepared by this method.

At the National Naval Medical Center, Bethesda, Maryland, much has already been achieved in the experimental investigation of tissue banking by freeze-drying. Blood-vessels, skin, and bone have been stored in this way. Marrangoni and Cecchini (1951) and Strong (1954) have reported their results after using freeze-dried material in a large number of abdominal aortic homo-

grafting operations in dogs; they believe them to be better than those obtained with fresh homografts. Hufnagel (1954) reports that the same has been true in his experience with 12 freeze-dried aortic and peripheral arterial grafts in patients. We have used such arteries in 27 patients with satisfactory early results.

We describe here a simple method of freeze-drying arterial grafts, and report some experimental observations on the process.

Technique PRINCIPLE

Sublimation of water vapour from the frozen state is greatly accelerated by reducing the total pressure of the surrounding atmosphere. The latent heat of vaporisation is derived from the material being dried, which is thus kept frozen. It is known that frozen solutions and suspensions must be kept below a certain temperature, which varies with the substance under examination, if separation of their constituents is to be avoided. The eutectic point of a mixed substance is the temperature above which one of its components separates out by melting; the greater part of the drying process should be done at a temperature which is below this. During freeze-drying, as the water content decreases, the temperature of the material rises towards that of its surroundings, but in other respects its composition remains constant.

METHOD

The method is based upon that used by one of us for drying purified diphtheria toxoid (Holt 1950) with much of the actual apparatus used in the early technique for small-scale production.

Grafts have been dried in the 'Pyrex' test-tubes in which they had originally been frozen, at -79°C , in several instances a year before. The rubber cap was in each case removed, and a piece of sterile gauze was secured in its place with a rubber band (to serve as a bacteriological filter when air was later readmitted to the system). The graft tubes were next placed in a glass container, attached by a standard vacuum fitting to a 2.5 or 3.0 litre glass condenser¹ (fig. 1), whose inner surface was kept at -79°C with a mixture of alcohol and solid carbon dioxide. The condenser outlet was connected by a length of $\frac{1}{2}$ -in. bore rubber pressure tubing to a single-stage rotary vacuum pump.² A secondary moisture trap containing phosphorus pentoxide was inserted between the vacuum line and the pump to prevent any remaining water vapour from entering it. The system was found with a Pirani gauge to operate at 0.030-0.060 mm. Hg during drying. With either pump a hard note was reached in a minute or less.

1. Edwards 'Speedivac 1A' (pumping capacity 39 litres a minute) and '1S.150' (144 litres a minute) were both used and proved completely satisfactory.
2. Penicillin freeze-drier: National Glass Industry Ltd.

Fig. 1—Apparatus used for simultaneous primary freeze-drying of up to six arterial grafts.

Primary drying.—Under these conditions it was possible to complete the primary drying of 1-6 assorted arteries during a working day. The grafts became slightly shrunken, hard, and pinkish white, and fell free from the wall of their containers, which on removal were found to be no more than cool to the touch. A few loose fragments of dried plasma were often present. Ice accumulated on the condensing surface was recovered next morning as water and was measured.

Secondary drying.—Much of the remaining moisture was extracted by placing the grafts, still in their gauze-capped tubes, in a vacuum desiccator over fresh phosphorus pentoxide. This container was evacuated by the pump for at least twenty minutes, and the vacuum was maintained for three days or more; except with large batches, little visible change developed in the phosphorus pentoxide during this time.

Final sealing.—Close-fitting rubber caps,³ autoclaved and vacuum-desiccated, were applied to the tubes, whose gauze filters were taken off on removal from the desiccator. A sterile hypodermic needle attached to the vacuum line was next inserted through each cap in turn, and the air was thus extracted until no further increase in the vacuum obtained could be detected by the high-frequency spark tester or by the note of the pump. The needle was next quickly withdrawn, and the cap covered in melted black 'Picien' vacuum wax. In very few instances has this seal failed. Tubes have been periodically examined with the spark tester and a final check made just before each graft was reconstituted for use.

Reconstitution.—Sterile isotonic saline solution was injected through the rubber cap until the tube was full; no air was admitted until the artery had regained its

normal appearance from twenty to thirty minutes later; it was then inserted into the patient or was used for the tests described below.

Experimental Observations

Bulk of Material to be Dried

An arterial tree, including the thoracic and abdominal aorta, the iliac, femoral, and popliteal arteries, and short lengths of their branches, weighed 67 g. With a large wide-necked drying tube of the type shown in fig. 1 most of the grafts prepared from such a specimen could be dried in one batch.

Examination of Condensate

Primary drying of the arteries mentioned above yielded a layer of ice on the condenser from which 37 g. of water was later recovered. This is more than the amount of water which it is practicable to remove with phosphorus pentoxide alone. For amounts greater than 15 g. a refrigerated condenser is more satisfactory but, unless mechanically chilled, needs closer attention.

Chemical analysis of the condensate showed a chloride content of 3 m.eq. per litre or less; no sodium or potassium could be detected by flame photometry. Some specimens of condensate were clear, others faintly opalescent. These were found to show a similar fluorescence on exposure to ultraviolet light to that obtained with vacuum grease.

Characteristics of Grafts after Reconstitution

Grafts reconstituted *in vacuo* with isotonic saline solution presented a normal fresh appearance. Histological examination showed no difference from control specimens of the same artery fixed in formalin and saline solution (fig. 2). This was true of sections stained with hæmatoxylin and eosin, with iron hæmatoxylin and van Gieson, and with elastic tissue stain.

Pressure-volume curves were constructed for three segments of human femoral artery with an apparatus constructed for us by Dr. S. Rowlands. It consisted of a mercury manometer connected by a T tap to a hypodermic syringe containing isotonic saline solution, and through a second and detachable tap to the segment of artery under examination, ligated at its free end. With each ml. of injected saline solution the increase in volume of the artery could be measured directly from its increase in weight. A curve from 0 to 250 mm. Hg was constructed for each of the three segments, and was repeated after each piece had been preserved for four weeks either by immersion in nutrient saline solution (Hanks and Wallace 1949) at 0°-4°C, or by freezing at -79°C, or by freeze-drying by the method described. The results are shown in fig. 3.

Effect of Varying Conditions of Drying

It was possible, through the coöperation of the Edwards Company, to subject three equal lengths of an

external iliac artery to the following treatment. After freezing by immersion in small capped bijou bottles in alcohol-carbon dioxide freezing-mixture at -79°C , one length of artery was dried for forty-seven hours without external cooling, the second length for six days at -30°C , and the third for fourteen days at -50°C . Each piece was then examined for residual moisture content, by the following method:

Moisture determinations.—The remaining water content of these and the other grafts examined in this investigation was extracted by a further process of freeze-drying in a micro-unit at Pirani pressures of about 0.015 mm. Hg. The vapour evolved was trapped in a narrow-bore glass U-tube immersed in alcohol and carbon dioxide at -79°C , and in equilibrium with an oil manometer in parallel with the vacuum line. The amount of ice thus condensed was next measured by closing a tap between the two limbs of the manometer and removing the cold trap, so that the ice reevaporised. Its pressure thus measured was converted into terms of weight by the mano-

TABLE I—EFFECT OF TEMPERATURE VARIATION ON DRYING OF ARTERIAL GRAFTS

Temperature of drying-chamber ($^{\circ}\text{C}$)	Time of drying	Residual moisture content by final dry weight (%)	Estimated amount of original tissue water removed (%)
20	47 hr.	0.83	99.9
-30	6 days	9.32	96.5
-50	14 days	100—i.e., processed specimen still contained a weight of water equal to its final dry weight	65.5

meter scale, which was calibrated in units of 0.00001 g. H_2O . When no more water could be extracted in this way, the now totally dry specimen was quickly weighed. The percentage residual moisture content could then be calculated.

Results obtained by this method confirm that arterial tissue dries rapidly at room-temperature, but below 0°C drying-rates become progressively slower as the temperature falls (table I). Samples taken during primary drying with a thermocouple in the wall of the artery were also examined for moisture content at known temperatures in this cycle. The results of these observations are shown in table II. The final moisture content of other arteries after secondary drying for seven days over phosphorus pent-oxide in a vacuum desiccator was found to be 2%; the transfer from desiccator to micro-drier necessarily involved a short exposure to atmospheric water vapour. This condition, however, is reproduced in the process of final sealing of grafts by the method described.

Thermometry during Freezing and Drying

The temperature of the tissue during freezing has an important bearing on its chance of physicochemical preservation, and during drying it indicates the stage which drying has reached. We have therefore recorded the temperature changes within the wall of several

Fig. 4—Thermocouple readings during freezing and freeze-drying of a femoral artery segment 2.5 cm. long. The peaks at the beginning and end of the primary drying cycle correspond respectively to the evacuation of the system and to the exposure of the graft to room air.

grafts throughout the cycle, using a very fine gauge thermocouple to reduce the error from conducted external heat. This confirmed what had been found by simple thermometry: freezing in an alcohol- CO_2 mixture at -79°C in an air-containing glass tube though not slow is not rapid either. A 2.5 cm. length of carotid artery, weighing 0.5 g., equilibrated with its surroundings at -58°C in five minutes, whereas a 5 cm. length of aorta, weighing 14 g., took fifteen minutes.

The same specimens were next subjected to rapid evacuation in the apparatus described, the thermocouple leads having been brought out through brass electrodes fitted into standard B.14 vacuum sockets. The results, indicated in fig. 4, prove that already frozen artery tissue

TABLE II—MOISTURE REMOVED FROM AND REMAINING IN ARTERIAL SEGMENTS AT VARIOUS STAGES IN DRYING PROCESS

Stage of drying in chamber at $20^{\circ}\text{C} \pm 2^{\circ}\text{C}$	Residual moisture content by final dry weight (%)	Estimated amount of original tissue water removed (%)
Specimen at -6°C in primary drying cycle	51.0	86.8
Specimen at 0°C in primary drying cycle	19.5	93.0
On reaching 20°C (end of primary drying)	4.4 } 3 specimens 5.1 } 5.3 } examined	99.2
After seven days' drying at 20°C	2.2 } 3 specimens 2.3 } 2.0 } examined	99.3

placed in the drying-chamber at a low temperature and quickly decompressed can be relied on to remain frozen by virtue of the rapid evaporation of water vapour alone. No external cooling need be used; in fact such cooling has already been shown to slow the rate of drying. Experiments of this kind also confirmed that a moderately large batch of arteries—e.g., the whole yield from one donor—can be taken through the stage of primary drying in about ten hours.

TABLE III—QUANTITATIVE EFFECT OF FREEZING AND FREEZE-DRYING ON BACTERIAL CONTAMINATION OF ARTERIAL GRAFTS

Control culture	Added bacteria	Method of processing graft	Result
10 segments taken aseptically; 7 lightly contaminated with <i>Staph. albus</i> (donor with type-II nephritis)	11.8×10^6 viable coliforms between 10 segments	Freeze-dried	Average per segment 340 organisms
10 segments; 7 contaminated with spore bearers (donor with pelvic peritonitis)	8.5×10^6 viable coliforms between 19 segments	10 Frozen and thawed 9 Freeze-dried	3×10^6 organisms 7/9 sterile 1 segment 100 organisms 1 segment 1200 organisms
10 segments taken aseptically; 2 contaminated with <i>Esch. coli</i> (donor with carcinoma of colon)	75×10^6 <i>Staph. aureus</i> between 20 segments	10 Frozen and thawed 10 Freeze-dried	20.3×10^6 organisms 2.1×10^6 organisms

Bacteriological Studies

Many bacteria survive freezing and thawing, and some also resist prolonged desiccation. Freeze-drying is one of the accepted methods of preserving bacterial cultures. If the moisture content of a dried culture is very low, and storage is prolonged, there is a progressive loss of viable organisms; in fact, measures must be taken to protect them (Proom and Hemmons 1949).

We therefore studied the effect of freeze-drying on a known bacterial contamination of human arterial grafts. Some arteries were taken aseptically, and others contaminated deliberately with known quantities of bacteria. Control cultures were obtained, and were later repeated on equal numbers of contaminated arterial segments after freezing and thawing, and after freeze-drying and reconstituting. The effects of these procedures on measured numbers of viable coliform bacilli and staphylococci are shown in table III.

These results indicate that the freeze-drying of arterial grafts by this process is an effective means of reducing bacterial contamination. But the grafts remain infected; therefore the need for careful selection of donors and an aseptic graft-taking technique still remains.

Discussion

This method of freeze-drying, though simple, yields a product which, after reconstitution, retains most of the properties of fresh material, judged by its physical and morphological characteristics. When it is applied to other substances—e.g., penicillin and purified diphtheria toxoid—which are assayable, good chemical preservation can be demonstrated.

Tissue is usually dried for histological purposes at -40°C or less. This is necessary if certain minute structural changes are to be avoided; but such drying takes much longer (table I). Complicated apparatus is needed to maintain the refrigeration of the drying-chamber and of the condenser during this long time, particularly if fairly large amounts of tissue are being dried.

One objection to drying with the chamber at room-temperature is the possibility of changes due to eutectic separation of water and other constituents. Table II, however, shows that, as the drying temperature rises, the water content rapidly falls, with the result that at -6°C about 87% of the original water has already been removed. It is therefore unlikely that the relatively small amount of water remaining will disturb the structure of the arterial segment, and the histological appearance of the reconstituted artery confirms that by this standard the method has been satisfactory.

It is important to select donors of arterial grafts for freeze-drying with particular care. Even early evidence of intimal or medial changes preclude the use of this method, since lipid material cannot be dried, and early changes in the tissue-proteins may lead to further denaturation during drying. We therefore apply stricter criteria to the selection of donors when the vessels are to be freeze-dried than when they are to be banked frozen.

Summary

A simple method of preserving arteries by freeze-drying is described.

Such arteries can be stored at room-temperature for an indefinite time.

In clinical practice freeze-dried transplants of large arteries have given results which in the early stage equal those of arteries preserved by other means.

We wish to thank Dr. R. D. Andrews, of the Wright-Fleming Institute, and Dr. G. W. D. Scott, of the department of morbid anatomy, St. Mary's Hospital, for their help with the bacteriological and histological studies respectively; and Dr. P. N. Cardew, of the department of medical photography, St. Mary's Hospital Medical School, for the photographs.

THE FATE OF BISMUTH CARBONATE IN THE STOMACH

A RADIOLOGICAL STUDY

F. PYGOTT

M.B. Lpool, D.P.H., D.M.R.E.

RADIOLOGIST, CENTRAL MIDDLESEX HOSPITAL, LONDON

THE therapeutic value of an alkali in the treatment of peptic ulceration appears to depend on at least six factors: chemical efficiency of the alkali; the absence of any after-secretion effect; the persistence of the alkali in the stomach under varying conditions; any protective effect it may have by adhering to the gastric mucosa, thus providing neutralisation of hydrochloric acid as it is secreted; any physical or chemical protective effect that it may have by persisting in the crater of an ulcer; and the absence of undesirable side-effects. With radio-opaque alkalis radiological methods can be used to examine with some degree of accuracy three of these factors—namely, the persistence of the alkali in the stomach, any adherence to the gastric mucosa, and the persistence in the crater of an ulcer.

There has been of late revived interest in the use of bismuth carbonate in the treatment of peptic ulcer, and Kemp (1950), Croxon Deller (1952), Douthwaite (1953), and Avery (1953) have reported favourably. Hence it seemed worth while to study the fate of this alkali when it was given in therapeutic dosage under different conditions to healthy people and to patients with either gastric or duodenal ulcer. Special attention was directed to its persistence in the stomach, its adherence to the gastric mucosa, and its retention in the ulcer crater in patients with recently proved radiological evidence of peptic ulcer.

The dose of bismuth carbonate used for the test-meals was 20 g. This dose is within the therapeutic range and is the alkali equivalent of about a third of the normal 24-hour secretion of hydrochloric acid. It was given in the form of a cream by whisking the bismuth carbonate powder in 2 oz. of water for a minute or so in a high-speed electric mixer. The cream could be swallowed easily from a medicine-glass, and any remaining in the glass was scraped out with a spoon.

Methods

It was decided to make each test examination on four persons, but in one of the groups of normal subjects five were included, and one patient in one of the gastric-ulcer groups also had a duodenal ulcer and therefore also appeared as a fifth patient in one of the duodenal-ulcer groups. The people examined were unselected. Two of the normal subjects (women) were used twice for different examinations after a fortnight's interval. None of the patients with peptic ulcer appear twice in the series, except the male with a double lesion. The normal subjects and the patients were examined fasting.

Tests

The tests made on normal persons were as follows:

(1) Bismuth carbonate 20 g. was given in 2 oz. of water, the subject being prepared as for a barium-meal examination.

(2) As in (1), but a few minutes after the bismuth had been given 6 oz. of water was drunk, and observation was continued.

(3) The bismuth carbonate was given on an empty stomach and followed by one egg beaten up in milk to a total volume of 6 oz.

(4) The bismuth carbonate was followed by an ordinary mixed meal.

(5) An ordinary mixed meal was given to the fasting subject, and then the bismuth carbonate was given.

(6) A mixture of 20 g. of bismuth carbonate in 6 oz. of milk was given.

The tests made on patients with gastric ulcer were identical with those enumerated above, except that test 2 was omitted. The tests made on patients with duodenal ulcer were limited to tests 4 and 5.

Radiological Examination

The gastric emptying-rate of bismuth carbonate, the adherence of bismuth carbonate to the gastric mucosa, and the persistence of bismuth carbonate in an ulcer crater were all likely to be affected considerably by the position adopted by the patient during the test and by the use of abdominal palpation. Accordingly it was decided to adopt the erect position throughout the examination, except for two normal subjects in test 1 and one normal subject in test 2, who were deliberately examined prone, the films being taken in that position. The patient or subject sat in a chair during the intervals between individual radiographic examinations. Abdominal palpation was deliberately avoided. The radiographic examinations were made rigidly to the time schedule previously arranged at fixed intervals of up to an hour after the start of the test. It was thought that the erect and sitting positions adopted throughout the test corresponded most nearly to those of a patient receiving ambulatory treatment for peptic ulcer. The erect position had the additional advantage that it facilitated estimation of the quantity of bismuth carbonate remaining in the stomach at the end of a given time.

At every stage of each investigation an attempt was made to assay the distribution and quantity of the remaining bismuth carbonate in the stomach, the presence of coating of the gastric rugæ, and the retention of bismuth carbonate in the crater of a gastric or duodenal ulcer.

Results

Normals

In the normal subjects there was a wide variation in the degree of retention of bismuth carbonate in all the tests except test 6 (bismuth-carbonate and milk mixture), in which nearly all the bismuth carbonate was retained in each of the five people at the end of an hour. Coating of the gastric rugæ was seen in those given bismuth carbonate only, in those who were later given water after their bismuth, and in three of the four people given a meal followed by bismuth, but in this last group the coating was slight. Flocculation took place in all the other tests except test 6, in which curds and not fine fragments were observed.

Gastric Ulcer

In the patients with gastric ulcer there was a lack of uniformity in all the tests in the rate of emptying of the stomach, and even test 6 showed considerable variation. Maximum retention took place in test 3, in which a mixture of egg and milk was given after the bismuth. Coating of the gastric mucosa was seen after a dose of bismuth carbonate given to the fasting patient, but did not persist for an hour in any of the four patients tested; it was infrequent in the other tests. Coating of the mucosa was only seen to persist for an hour in one of the twenty patients with gastric ulcer examined in the five different tests. Flocculation was present in

every test except test 1, in which bismuth carbonate was given alone; temporary coating was observed in this test. In fourteen of the twenty patients the ulcer crater was recognisable an hour after the test had begun, owing to the bismuth carbonate retained in it, but the amount of bismuth retained in the crater was no more than a trace in seven of these patients.

Duodenal Ulcer

In the patients with duodenal ulcer there was again a lack of uniformity in the rate of disappearance of bismuth carbonate from the stomach. The bismuth was usually retained longer in the stomach in patients given the bismuth after a meal of food than in patients given bismuth on an empty stomach. Flocculation rather than true coating of the stomach was present under the conditions of experiment. In only two of the nine patients examined was the duodenal ulcer crater recognisable an hour after the start of the test.

Conclusions

From these results it is evident that the retention of a significant quantity of a 20 g. dose of bismuth carbonate varies greatly from person to person under the same conditions. In a healthy person the retention is greatest when the bismuth is given in a milk mixture. True coating of the gastric rugæ persists only to a significant extent when bismuth carbonate is given as a suspension on an empty stomach, but it may occur to a slight extent in other circumstances. Flocculation of bismuth in the stomach is more common than coating.

Ten of the twenty patients with gastric ulcer retained half or more of the bismuth in the stomach under various conditions of test for an hour, but the emptying-rate was not uniform. Coating of the rugæ was exceptional at the end of an hour. Bismuth was retained in the ulcer crater in nearly three of every four patients, but in only one of every four was this retention considerable.

In patients with duodenal ulcer the rate of disappearance of bismuth carbonate from the stomach was more rapid than in gastric-ulcer patients. In the small number tested only three of the nine had half or more of the bismuth remaining in the stomach at the end of an hour. Flocculation of bismuth and not coating of the gastric mucosa took place in every patient in the two tests after half an hour. Retention of bismuth carbonate in the ulcer crater was uncommon.

It is evident that the effectiveness of bismuth carbonate as an alkali given in large dose at infrequent intervals is likely to vary considerably from patient to patient as well as with the circumstances of administration. It seems that, when the bismuth is given in milk or is followed by egg and milk, its retention in the stomach will be maximal. There is also some evidence in favour of giving it after a meal rather than before. It is clear that any protective effect exerted by direct contact with an ulcer surface is likely to be small.

Summary

Experiments are described in which radiography was used to examine the retention of bismuth carbonate in the stomach, its adherence to the gastric mucosa, and its retention in peptic ulcers.

Ten of twenty patients with gastric ulcer retained half the test dose of 20 g. of bismuth carbonate in the stomach for an hour irrespective of the method of administration. Three of nine patients with duodenal ulcer retained half the test dose for an hour.

Persistent coating of the gastric mucosa for an hour occurred only once in twenty patients with gastric ulcer, and did not occur in nine with duodenal ulcer, and is thus unlikely to be an important factor in the effectiveness of the alkali.

The ulcer crater was persistently outlined by small amounts of bismuth carbonate in fourteen of twenty patients with gastric ulcer, and two of nine with duodenal ulcer.

There is evidence in favour of combining bismuth and milk as a mixture or following it with egg and milk to prolong the retention of the alkali in the stomach. In duodenal-ulcer patients retention in the stomach is also more likely if the alkali is given after a meal.

THE rational treatment of hæmophilia aims at raising the blood level of antihæmophilic globulin (A.H.G.) to the point at which coagulation can become hæmostatically effective. This is usually attempted by transfusing blood or plasma or by injecting a concentrated preparation of A.H.G. In practice, therapy is hampered by uncertainty about the activity of available preparations, the minimal blood-level required, and the duration of any increase produced. All these troubles can be traced to the difficulty of measuring A.H.G. activity. Assay methods used hitherto determine A.H.G. activity from the amount of material required to correct the clotting-time, prothrombin consumption, or thrombin generation (Pitney and Dacie 1953) of hæmophilic blood. They thus depend on a supply of hæmophilic blood; and, since this is seldom continuously available in the laboratory, the tests which could be made were limited. For this reason there have been relatively few observations on the blood-levels of A.H.G. which might indicate the physiological minimum, apart from those of Brinkhous et al. (1954) who used hæmophilic dog blood. Experimental work on the purification of A.H.G. has also been greatly restricted, since at every stage the activity of the product should be tested if systematic progress is to be made.

The thromboplastin-generation test, introduced by Biggs and Douglas (1953), has removed these restrictions since it can be modified to assay A.H.G. and requires only constituents derived from normal blood. This application, which will be published later, has allowed many measurements of blood-A.H.G. levels to be made. From these findings and those of Brinkhous et al. (1954), Pitney and Dacie (1953), Graham et al. (1953), and Baserga and de Nicola (1951) it can be deduced that 30-50% of the normal amount of A.H.G. in the blood is needed for reasonable hæmostatic efficiency. Usual estimates of the therapeutic level are much lower than

these (Wright et al. 1948) because restoration of the clotting-time to normal is often taken as the criterion, and 2-5% of the normal amount of A.H.G. in the blood is probably sufficient for this in most hæmophilic patients. In cases in which dosage has been controlled by determining the clotting-time the real therapeutic levels of A.H.G. have seldom been reached, and the patients have often continued to bleed. It follows that the proper treatment of a hæmorrhagic episode and the prevention of bleeding after a minor operation will involve the use of much larger amounts of blood or of A.H.G. than are usually given.

In view of the limited supply of human blood we decided to investigate the possibility of using A.H.G. derived from animals. Patek and Taylor (1937) showed that plasma fractions active in correcting the clotting time of hæmophilic blood could be obtained from the blood of the sheep, ox, rabbit, and monkey. Pohle and Taylor (1938) used an ox-blood plasma fraction as a local hæmostatic to control hæmophilic bleeding. Spaet and Kinsell (1953) produced a bovine A.H.G. preparation by a method based on the Cohn process but did not use it clinically. Lorand and Laki (1954) have prepared material with A.H.G. activity from dog and ox blood by adsorption on to kaolin. Our own work has also been mainly concerned with ox blood, which is available in large quantities from the slaughter-house, and which we found to have an average A.H.G. activity sixteen times that of human blood. Pig, horse, and sheep blood have been investigated but are less active.

Many experiments were made to improve methods for extracting and purifying bovine A.H.G., the results being checked by frequent assays of activity. The best material has been produced by salt fractionation, and, though losses have been unaccountably variable, enough bovine A.H.G. has been prepared to allow a study of its effects on animals, and a trial in man. Details of the method of preparation will be published in another paper. The material has an activity equivalent to about 20 pints of normal blood per g. of protein; it is far from "pure," containing a large proportion of fibrinogen. It maintains its activity indefinitely in the dried state, but quickly deteriorates in solution. When the publications by Spaet and Kinsell (1953) and Lorand and Laki (1954) appeared, the methods described by them were used in parallel with our own but were found to yield less active material.

Before bovine A.H.G. was used clinically certain investigations were necessary. The assay of activity, which had been based on the thromboplastin-generation test, was confirmed by finding the expected ability to correct the prothrombin consumption and thrombin generation of hæmophilic blood *in vitro*. Sterilisation of the A.H.G. in solution presented some difficulty, since it was heat-labile, lost activity on Seitz or Berkfeld filtration, and could not be passed through a gradocol membrane. Sterilisation was finally achieved by centrifuging at high speed, followed by measured exposure to ultraviolet light, the solution being contained in a rotating quartz tube. Toxicity was investigated by injecting the material into mice and rabbits. The mice each received an intraperitoneal injection of about 100 times the human dose in proportion to body-weight. 30 mice survived without obvious ill effects, but a batch of 5 died, about two weeks after injection, with kidney lesions indicating nephrosis, these 5 animals having received material which had been denatured and partially coagulated by accidental overexposure to ultraviolet light. One rabbit received 1 g. of material by intravenous injection in three doses in six weeks and showed no ill effects.

The clinical action of the material was next studied in three hæmophilic volunteers. The results were judged

* In receipt of a grant from the Medical Research Council.

† Supported by a grant from the Nuffield Foundation Hæmatological Research Fund.

by the effect on clotting after intravenous injection and by the amount of hæmorrhage after dental extraction. Since an obvious disadvantage of the use of animal protein is the development of antibodies, tests for their presence were made on all three volunteers.

Methods

The *clotting-time* was measured by a modification of the Lee and White method (Biggs and Macfarlane 1953), the normal range being 3–10 minutes. The *prothrombin-consumption index* was measured by the method of Merskey (1950), the normal range being 0–40%. *A.H.G. activity* was measured by a modification of the thromboplastin-generation test of Biggs and Douglas (1953), which will be published later. *Platelet-agglutination* tests were made on a mixture of the test material and human citrated blood incubated for ten minutes and then hæmolyzed with ammonium oxalate and observed in a counting-chamber by phase-contrast microscopy.

Results of Clinical Trial

All three patients were admitted to the Radcliffe Infirmary under the care of Dr. P. C. Mallam.

Case 1 (Reg. no. 32036).—A man, aged 43, with the family and personal history typical of hæmophilia, had spent much of his life in hospital with hæmaturia, hæmatemesis, hæmarthroses, and hæmorrhage in the deep tissues requiring many transfusions. Previous dental extractions had led to prolonged hæmorrhage and required the transfusion of 42 pints of blood in all, but on one occasion there was only slight bleeding and no transfusion was needed.

Trial.—At the beginning of the trial a skin test was made with bovine A.H.G., which gave no reaction. A small intravenous dose of the material was next given with no observable ill effect. Next day A.H.G. 0.5 g. was injected intravenously, producing no untoward reaction apart from a transient sensation of tingling of the lips. A general anæsthetic was given thirty minutes later, and the stump of a carious molar tooth was removed by Mr. C. Annand Smith, and the socket was scraped. There was very little bleeding at operation, and this stopped within a few minutes, the socket becoming filled with firm clot. At seven hours after the extraction there had been no bleeding, and a further dose of A.H.G. (0.8 g.) was injected. The socket healed completely within ten days without hæmorrhage.

Laboratory findings.—Before treatment the patient's clotting-time was 12–15 minutes and prothrombin-consumption index 70–120%. The blood-A.H.G. level was less than 1%. After the first injection the A.H.G. level rose to 35%. Seventeen hours after the second injection it had fallen to 5%, but the clotting-time and prothrombin consumption remained normal. By next day, forty-three hours after the last injection, the clotting-time and prothrombin consumption had reverted to the untreated levels.

Case 2 (Reg. no. 188647).—A man, aged 38, had the typical history of hæmophilia. Three brothers are also affected. He had been in hospital many times with hæmaturia, hæmarthroses, and mælena, requiring many transfusions. One tooth had been removed previously, after which he had bled for fourteen days but did not require transfusion.

Trial.—An intradermal skin test with bovine A.H.G. gave no reaction. Next day A.H.G. 0.4 g. was given intravenously, and thirty minutes later a general anæsthetic was given and a carious premolar tooth was removed by Mr. C. Annand Smith, and the socket was scraped. There was little bleeding at the time of extraction, and the socket was dry and filled by a clot within about thirty minutes. A second dose of A.H.G. (0.5 g.) was given eight hours after the extraction, and a third (0.5 g.) twenty-six hours after the second. During each injection the patient experienced "specks and flashes of light" in the eyes but no other sensations and no constitutional disturbance. There was no bleeding until four days after the last injection, when there was slight oozing around the clot, which stopped spontaneously in a few minutes. Two days later the clot became detached and the socket was found to have healed beneath it.

Laboratory findings.—Before admission this patient had been investigated by Dr. J. V. Dacie, of the Postgraduate

Fig. 1.—Changes in A.H.G. level and in prothrombin-consumption index, expressed as percentage of normal, during treatment of case 2 with bovine A.H.G. Interrupted line indicates probable changes after second injection of A.H.G., no readings having been made in this period.

Medical School, London. Some of the laboratory investigations made during the trial are summarized in fig. 1. Before treatment the clotting-time was 26–35 minutes, and the prothrombin-consumption index 160%. After the injections the clotting-time was maintained within the normal range until twenty hours after the last injection. The blood-A.H.G. level was maintained for only a relatively short time after the injections, having fallen to 5% of normal within seven hours, and to 2% after twenty hours. The prothrombin consumption fell to 21% after the first injection, but after the third it unexpectedly rose slightly instead of falling, although the blood-A.H.G. level had risen.

Case 3 (Reg. no. 189223).—A hæmophilic, aged 34, with four affected brothers and one affected nephew, had been admitted to hospital many times with hæmarthroses and required transfusions on losing his primary teeth. At the age of 23 he had sixteen teeth removed in one operation and bled for six weeks, requiring the transfusion of some 40 pints of blood. At the age of 26 he had a transient left hemiplegia, and later one epileptic attack. Since this time he has been treated with 'Epanutin' and phenobarbitone. On admission for the trial he was most anxious to have all his remaining sixteen teeth removed, since many of them were grossly carious and causing trouble. With some reluctance it was agreed to comply with his wishes.

Trial.—An intradermal skin test made with bovine A.H.G. was negative. Next day the volunteer was given A.H.G. 0.4 g., and fifteen minutes later the sixteen teeth were removed under general anæsthesia by Mr. J. M. Helsby. Bleeding was not excessive at operation, but throughout the day there was persistent oozing from all tooth sockets despite two further injections of A.H.G. totalling 0.8 g. In the evening dental splints lined with alginate soaked in 'Stypven' (Russell's-viper venom) were fitted, and the bleeding stopped. During the next three days there was no bleeding and three injections of A.H.G. were given totalling 1.3 g. At each injection the patient experienced "light-flashes" in front of his eyes. Treatment with A.H.G. was then stopped because severe thrombocytopenia was discovered at this time. On the fourth day after extraction the dental plates were removed, and the sockets were found to be dry and to be filled with firm clots. Throughout the following two days there was no bleeding. On the sixth day after extraction (three days after the last injection) slight oozing started first from one and then from several sockets. This was readily controlled by light pressure and Russell's-viper venom. It recurred, however, from time to time for a further seven days but was always controllable, and transfusion was not considered necessary, though the Hb level fell to about 50%. The sockets healed within fourteen days but in the next three weeks developed several blood-filled overgrowths of granulation tissue which required excision, the operation being covered

Fig. 2.—Changes in A.H.G. level and in prothrombin index expressed as percentage of normal, during treatment with bovine A.H.G.

by the transfusion of 3 pints of fresh blood and $7\frac{1}{2}$ pints of fresh plasma. These superficial blood-cysts may possibly have been related to the effects of epanutin.

Laboratory findings.—This patient had been previously investigated by Dr. E. K. Blackburn, of the Royal Infirmary, Sheffield. Some of the findings obtained during the trial are summarised in fig. 2. Before treatment was started, the clotting-time was 13 minutes and the prothrombin-consumption index 37%. The clotting-time decreased to normal after the first injection and remained within normal limits for five days. The results of the prothrombin-consumption tests were both unexpected and disturbing (fig. 2), since after each injection of A.H.G. the index rose above its pre-injection level. This rise was inexplicable until it was discovered, after the fifth injection, that the patient's blood contained no platelets. During the night which followed this injection the platelets increased to 33,000 per c.mm., and after the sixth and final injection they decreased again almost to zero. Since the decrease in the platelet-count appeared to be directly related to the injection of A.H.G., treatment with this material was then stopped. After the last injection the platelet-count increased by an average of 22,000 per c.mm. a day until it reached the normal range. During the period of thrombocytopenia there were no hæmorrhagic manifestations of the purpuric type, and the bleeding-time determined by needle punctures in the ear lobe was normal. Another feature of this case was the fact that the blood-A.H.G. level was kept higher than in either of the two other patients.

Other Investigations

Antibodies

In each patient tests for the presence of antibodies were made at three and six weeks after the dental extractions. Incubation of the patient's plasma with bovine A.H.G. caused no loss of the activity of A.H.G., suggesting that specific antibodies to A.H.G. had not developed to any significant extent. Intradermal skin tests gave very slight positive reactions in cases 1 and 2 and negative reactions in case 3. Precipitin reactions, done by Dr. A. C. Allison, gave weakly positive reactions between the patients' sera and A.H.G. dilutions in all three cases.

Platelet Agglutinins

Bovine A.H.G. agglutinated human platelets but had no effect either on human red cells or on rabbit platelets. Platelets were agglutinated by concentrations as low as 0.125 mg. of protein preparation per ml. of blood; hence the injection of 0.5 g. of A.H.G. would allow an agglutinating concentration to be reached in vivo. The platelet agglutinin was also present in the ox plasma. When re-examined some weeks after their injections the platelet-counts of cases 1 and 2 were normal.

Effect of Oral A.H.G.

Ten days after dental extraction case 2 ate 2 g. A.H.G. in powder form mixed with cereal. Clotting-times and

blood-A.H.G. levels estimated at intervals during the following twenty-four hours indicated that no active material had been absorbed into the blood-stream.

Discussion

The principal reason for using an animal source of A.H.G. was the realisation that supplies of human blood must be inadequate for the effective treatment of hæmophilia. A hæmophilic adult probably requires the administration of an amount of A.H.G. contained in 5 pints of blood to achieve temporary hæmostatic normality, and studies of the survival of both human and bovine A.H.G. in hæmophilic blood indicate that this dose must be repeated daily to maintain the effect. Even if this treatment is used only in cases of actual hæmorrhage, or to cover a minor operation, very large amounts of blood would be required. Failure to attain the therapeutic level will lead to the use of still more blood, because continuous bleeding will cause further loss of A.H.G. Case 3, after a previous dental extraction, had received some 40 pints of blood but bled for six weeks. Incidents such as these put a great strain on an already overloaded transfusion service.

The ultimate goal of treatment with A.H.G. is continuous replacement, as in the treatment of pernicious anæmia with vitamin B₁₂, and of diabetes with insulin. Only in this way can the patient be maintained in a normal state and the danger of internal hæmorrhage and hæmarthroses avoided. But such maintenance therapy would be impracticable if only human A.H.G. were available, since it would need a special panel of about 500,000 donors to treat the 500 hæmophiles estimated to exist in this country. It would be quite practical if the A.H.G. could be derived from ox blood, which is about sixteen times as active as human blood and is available in ample amounts.

This preliminary clinical trial of a preparation of bovine A.H.G. is sufficiently promising to warrant further active investigation. Its administration to three hæmophiles produced the expected effect on clotting, which was in each case restored to a physiologically effective level for several hours after each injection. In cases 1 and 2 there was virtually no bleeding after dental extraction, a result which previous experience demonstrates must be highly significant. In case 3 the removal of sixteen teeth at the patient's own wish was a severe test, and there was fairly brisk bleeding for the first few hours after extraction. In this case, however, there was the later recognised complication of thrombocytopenia; and the fact that no transfusion was necessitated by the postoperative hæmorrhage indicates that even the curtailed course of A.H.G. therapy must have had a considerable beneficial effect.

The general objection to the use of animal material is its antigenicity. Injections of ox-plasma protein will probably induce the formation of antibodies and lead to the danger of allergic reactions on further injections. Our own material seems to have produced slight sensitisation, since only doubtfully positive skin tests and precipitin reactions have been obtained during the weeks following the therapeutic trial. The bovine A.H.G. used by us therefore seems not to be a powerful antigen—a point which is being investigated by experiments on animals. If better purification is achieved, the antigenicity may be reduced further. The nature of the anti-hæmophilic factor is unknown; it might be a substance which, like insulin, is relatively non-antigenic.

The specific objection to the preparation used in this trial is its power to agglutinate human platelets in vitro and the occurrence of profound thrombocytopenia in the one patient in whom platelet-counts were made after its use. It is not known if a similar effect was produced in the two other patients, because, there being

no reason to suspect thrombocytopenia, platelet-counts were not made after the injections. But an increase in the prothrombin-consumption index after injection in case 2 suggests that the platelet-count may have been reduced in that case also. Although the temporary thrombocytopenia in case 3 produced no apparent ill effects and caused no purpura it was felt to be a sufficiently serious complication to postpone further human trials with bovine A.H.G. until more information on the nature of this effect is obtained. Inter-species platelet agglutinins have been described by Mushett et al. (1953), and these could be separated from other agglutinins by fractionation of the plasma. It may prove possible to separate the antihæmophilic effect from the platelet-agglutinating activity. If this is so, more extensive trials of the material will be made.

Summary and Conclusions

The effective treatment of hæmophilia by replacement of the deficient factor requires large amounts of blood not easily obtainable from human sources.

Bovine blood has about sixteen times the antihæmophilic activity of human blood, and enough would be available for the continuous treatment of the whole hæmophilic population of this country.

A preparation of bovine antihæmophilic globulin has been produced, of which 1 g. has an activity equivalent to about 20 pints of normal human blood, assayed by the thromboplastin-generation test.

Three hæmophilic patients received intravenous injections of this material, with the expected rise in the antihæmophilic activity of their blood.

In two cases so treated dental extraction produced no abnormal bleeding. In the third case the removal of sixteen teeth caused bleeding for several hours but did not necessitate transfusion.

No ill effects were observed in the first two cases. In the third case the injections produced thrombocytopenia but no purpura.

The bovine material used agglutinated human platelets, and attempts will be made to eliminate or reduce this action before proceeding with further trials in man.

The material has shown some slight antigenic properties, which it is hoped may be reduced as purification methods are improved.

We wish to thank Dr. A. H. T. Robb-Smith for his encouragement and valuable advice; the three volunteers for their courageous coöperation; Dr. P. C. Mallam for admitting the three volunteers to his wards, his acceptance of clinical responsibility, and the help given by his staff; Messrs. Metropolitan Vickers for advice on sterilisation by ultraviolet light and for lending us the necessary equipment; Dr. B. R. Frisby, of the Oxford Regional Public Health Laboratory, for the sterility tests; and Mr. C. Annand Smith and Mr. J. M. Helsby for the dental extractions. We gratefully acknowledge the technical assistance of Mrs. J. Eveling and Miss G. Richards.

ANGINA OF EFFORT USE OF HEPARIN FOR ITS CONTROL

F. HARWOOD STEVENSON

M.D. Lond., M.R.C.P.

PHYSICIAN, ROYAL NATIONAL ORTHOPÆDIC HOSPITAL AND
BUSHEY AND DISTRICT HOSPITAL

D. G. WILSON

MEDICAL OFFICER, BUSHEY AND DISTRICT HOSPITAL

RECENT work has suggested a relation between the amounts of certain classes of lipoprotein molecule in the plasma and a tendency to atheroma (Gofman et al. 1950, 1951, Jones et al. 1950). In particular, an increase of lipoprotein molecules in the Sf 10-30 range has been associated with the development of atherosclerosis in both animals and man (Lindgren et al. 1951). The possible relation of these abnormal lipoprotein patterns to myocardial infarction and anginal pain is of considerable practical interest.

Graham et al. (1951) claimed that in cholesterol-fed rabbits the quantity of large-molecule lipoproteins in circulation was reduced by a single injection of sodium heparin intravenously. Daily injections of heparin to half of a group of rabbits on an atheroma-producing high-cholesterol diet had a protective action. Of the group receiving heparin, only 3 out of 20 showed atherosclerosis, whereas of those not so treated 15 out of 20 developed gross atherosclerosis.

Lyon et al. (1951) reported a higher rate of myocardial infarction and of angina of effort when the Sf 10-20 concentration was highest (Svedberg unit range of rate of migration in the ultracentrifuge). They added that in coronary disease low-fat low-cholesterol diets reduced the Sf 10-20 level and considerably reduced the occurrence of new myocardial infarction. Also, in 30 out of 32 patients with angina of effort pain was relieved for 3-10 days by a single injection of heparin 20-100 mg.

This was confirmed by Donzelott and Kaufmann (1952), and Basud and Stewart (1950) concluded that heparin lowered the plasma-cholesterol most when the initial figure was high. Ethyl bicouacetate ('Tromexan') as an alternative anticoagulant had no effect on the blood-cholesterol level. In a series of cases in which the plasma-cholesterol range was 200-268 mg. per 100 ml., the total cholesterol fell by 20-60 mg. when heparin was given.

Graham et al. (1951) described a clearance of lipid particles in human plasma in vivo by heparin. They treated atherosclerotic patients by twice-weekly injection of heparin 50-100 mg. intravenously or intramuscularly, and of their 59 patients who had angina of effort (45 had had a definite coronary thrombosis) 55 obtained great benefit and needed far less nitroglycerin.

A Clinical Investigation

We felt that the possible value of heparin for the relief of anginal pain deserved further investigation and that this could well be undertaken by a group of general practitioners. Most practitioners have several patients with angina of effort whose behaviour, trinitrin needs, and so on, are well known to them. In view of the statement that great relief of pain followed a single injection of heparin, we thought that with twice-weekly intramuscular injections of 100 mg. for one month any benefit gained should be apparent. As an additional check the following sequence of courses was given so as to see whether there was any detectable difference when heparin was administered and when it was omitted. (Procaine was included because intramuscular injection of heparin is painful.)

1. Twice-weekly intramuscular injection of 100 mg. of heparin, with 0.5 ml. of 1% procaine, for four weeks; followed immediately by

2. Twice-weekly injection of 1 ml. physiological saline solution, with 0.5 ml. of 1% procaine, for three weeks; followed immediately by

3. Twice-weekly injection as in the first period, for five weeks.

L.V.1 +, &c., refers to enlargement on a scale of 1 for minimal and 4 for maximal enlargement of the left ventricle observed on radiocopy.
N.A.D. = nil abnormal detected.

The changes of treatment were of course made without the patient's knowledge.

Before treatment began a careful history was taken, with full clinical examination, X-ray cardioscopy and barium swallow, electrocardiogram, and estimations of serum-cholesterol and hæmoglobin. Particular attention was paid in the history to the trinitrin requirements, the amount of exercise normally taken, the severity of the pain, and the threshold of onset. As far as possible the cases chosen for treatment were stable in their use of trinitrin. Total-cholesterol estimations before and after treatment were made, in view of the statement of Ancel Keys (1951) that these give a more useful indication of the likelihood of atherosclerosis and coronary disease than do estimations of particular fractions. The general practitioners kept records of their patients' comments at different stages, and at the end of the test the patients' condition was again fully investigated.

In the accompanying table, which summarises the findings, the figures in the last column are to be interpreted as follows:

1. Great improvement, both in degree of pain and ease of production with increased exercise tolerance (4 cases).
2. Improvement, but qualified by a greater degree of care on the patient's part, or by concurrent loss of weight (6 cases).
3. Doubtful improvement (5 cases).
4. No change (4 cases).
5. Worse. 1 stopped treatment after three injections as he had unpleasant reactions; 1 stopped after five weeks because he felt he was being made worse; and a 3rd developed an infarct during treatment. It will be realised of course that heparin was not being given as a continuous anticoagulant.

Only 1 man, out of the 10 cases improving, noticed any difference when the saline injections were substituted. This is directly contrary to the experience of Graham et al. (1951) who found in 9 cases that the pain rapidly returned when heparin was stopped.

No consistent effect on the total-cholesterol levels was evident. Indeed in half the cases the level rose during the course; nor was there any strict correlation between serum-cholesterol change and clinical improvement. Radioscopy with swallowed barium demonstrated no hiatus hernias in this series. (We are indebted to Dr. J. Rabinowitch, radiologist to the Bushey and District Hospital, for his radiological help.)

Conclusions

1. Heparin in the dosage used had no consistent demonstrable effect on the electrocardiogram, on the serum-cholesterol (total) or on the blood-pressure.
2. The apparent effect on the pain of half the patients suggests that the method deserves trial where pain is frequent and easily produced. No more can be claimed than this.

The following general practitioners took part in this investigation based on a hospital where some of them are members of the staff:

CHOLECYSTECTOMY

A METHOD FOR THE DIFFICULT GALL-BLADDER

WILLIAM A. McELMOYLE

M.D. Manitoba, F.R.C.S.E., F.R.C.S. (C.)

SURGEON, ROYAL JUBILEE HOSPITAL, VICTORIA, B.C., CANADA

FOR the patient, traumatic stricture or damage to the bile-ducts is a tragic and perhaps fatal accident; to the surgeon a deep and humiliating disappointment; and to the one who attempts reconstruction a formidable and oft recurring trial of strength and endurance leading to failure or death to a considerable number of patients. Consequently any procedure that will protect the ducts from damage merits consideration and trial. I describe here a method which has been tried in a limited number of cases for some years and has proved safe and rational even in difficult and troublesome situations.

As Maingot (1948) says, "When access proves difficult or the parts concerned in the operation have not been clearly visualized, excision of the gall-bladder is always a hazardous undertaking." One of the main hazards in the difficult gall-bladder is the dissection of the structures at the neck. Here, owing to the inflammation, the structures cannot be readily exposed, especially above and to the left of the infundibulum and neck. In these circumstances accidents may happen and bleeding be excessive, requiring the blind application of forceps in a field flooded with blood. This type of case is often

Fig. 1—Forceps placed on fundus in preparation to opening gall-bladder down broken line. Heavy oblique line is "imaginary line" mentioned in text. Heavy oval line encloses "dangerous area."

complicated by a previous duodenal or colonic fistula, the gall-bladder being contracted and fibrosed, and its wall thickened, with a tendency to be as tough as cartilage. Here it is often decided to do a drainage operation for the present, to be followed by removal later.

Because benign strictures virtually always follow surgical trauma, prevention of them is all-important. Flickinger and Masson (1946) observe that cholecystostomy and choledochostomy appear to be of minor importance as agents responsible for damage to the bile-ducts.

The reason for describing this operation is the increasing incidence of damage done to the bile-ducts. Waugh et al.

Fig. 2—Typical postoperative temperature and pulse-rate.

(1952) at the Mayo Clinic reported 83 cases repaired in 1951—a 46% increase over the total for 1950.

In the present operation no attempt is made to dissect out the cystic artery or the cystic duct. The branches of the artery are stitched over as they ramify in the remaining gall-bladder wall. The cystic duct is not tied; its mucosa is fulgurated at its opening into the gall-bladder. Biliary fistula has not developed in any of the 23 cases done by this method. If no dissection is done above and to the left of the imaginary line shown in fig. 1, and all operating is done to the right and below this line, no possible damage can be inflicted on the ducts or vessels. To do this, one is obliged to leave in situ the cystic duct and part of the gall-bladder wall—i.e., that portion of the neck, infundibulum, and body lying above and to the left against the liver bed. This acts as a shield to the vulnerable structures. Apparently this can be done with safety, provided that the mucosa is destroyed with phenol or with the electric cauterly.

This operation should not be confused with that practised and recommended by Pribram (1939), Love (1947), and Thorek (1936), who do the usual dissection of the neck, displaying the cystic duct and artery, and ligating and cutting the duct and artery as in retrograde cholecystectomy. They then leave in that portion of the gall-bladder wall attached to the liver, and fulgurate or coagulate its mucosa to avoid postoperative abdominal drainage which they consider harmful. I feel that, if the ducts and artery can be safely dissected out, conventional cholecystectomy should be done.

To date I have done 23 cases by this method, an average of about 2 cases every three years. On reviewing the records of the last 100 gall-bladders operated on by me at the Royal Jubilee Hospital, in Victoria, I find that 9 were done with the electric cauterly and 2 with phenol cauterisation of the mucosa. These 23 cases have all done well, and there have been no complications, fistulae,

Fig. 3—Forceps applied down wall, and gall-bladder opened further.

abscesses, or late sequela. Fig. 2 shows typical postoperative reactions of temperature and pulse-rate.

Possibly I do this operation more frequently of later years because I have confidence in its safety. It is done in any case where serious difficulties are anticipated in dissecting out the structures at the neck of the gall-bladder.

In planning this operation due regard has been paid to the possible presence of abnormalities. Flint (1923), reviewing the anatomy of the bile-ducts and vessels in 200 cases, found only 69 that agreed with the so-called

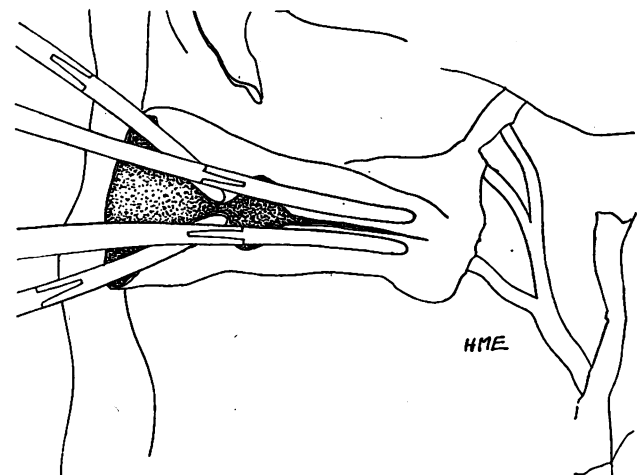

Fig. 4—Gall-bladder being opened toward neck between forceps.

Fig. 5—Interior of gall-bladder fully exposed in preparation for excision of wall.

normal anatomy of the textbooks. Only one common abnormality is involved, and it is no particular problem and will be discussed later.

THE OPERATION

When it is decided to do this operation instead of the usual cholecystectomy, the fundus of the gall-bladder is grasped with a pair of artery forceps (fig. 1), and an opening is made into its cavity, the bile is aspirated, and any stones are removed. Two pairs of artery forceps are applied down the wall on its free side (fig. 3), and a further incision is made between them with scissors. This cutting between forceps is continued until the region of the cystic duct is reached, any further stones being removed (fig. 4). The duct is next identified from within the cavity of the gall-bladder and is probed for stones and, if necessary, slit up over a narrow grooved director, the surgeon always cutting below and to the right. By carefully proceeding down the cystic duct

Fig. 6—Starting excision of redundant wall.

the common duct can be opened if this is thought to be advisable. One should not hurry at this stage of the operation. When the common duct is reached, the incision passes downwards along its course, any necessary manipulations for clearing the duct are undertaken, and a catheter or T tube is inserted and fixed in the usual manner.

We now have the gall-bladder laid open and held by a series of forceps around its edge (fig. 5). Starting at the region of the neck, curved forceps are applied as in figs. 6-8, care being taken not to attempt a too generous removal of the wall. Forceps are only applied to that portion which can be exposed readily from within and from without. After the application of these forceps excision of the excess wall is begun and continued until all the excess wall is removed. Usually the portion remaining is from half to three-quarters of

the upper left wall, which is normally attached to the liver bed.

Figure-of-eight double-O chromic catgut sutures are next inserted round the edge of the remaining gall-bladder wall, the forceps being removed as the sutures are tightened (fig. 9). This controls all bleeding. Only the mucosa remains to be dealt with.

If phenol is used it is applied with a tightly rolled applicator to prevent flooding, and the whole area is gone over several times, great care being taken in the region of the cystic duct. Alcohol and saline solution are applied after the cauterisation with phenol.

With the electric cautery a needle-pointed electrode is used, and all the mucosa is treated with a low current, care being taken not to be too thorough or vigorous and not to cauterise the interior of the cystic duct to within 5 mm. of the common duct. The mucosa should be superficially charred at completion. At no time should the needle be forced into the tissues to coagulate deeply. Any residual bleeding points around the edge are next touched with the needle. Personally I prefer the electric cautery, but I can see no difference in the results of the two methods. Phenol was used originally for convenience. The electric cautery is more controllable. With phenol there is always the potential danger that

Fig. 7—Further excision of wall.

some of it may accumulate in the cystic duct and eventually make its way into the common duct. When the cauterisation of the mucosa has been completed, a 1-inch soft rubber drain is inserted and held in position with one triple-O chromic catgut stitch placed in a convenient portion of the cut edge of the gall-bladder wall. A small catheter is placed down to the subhepatic space for the instillation of a suitable antibiotic after the skin is closed; this is not an essential part of the operation, and naturally was not used in the earlier cases. Little difference can be seen by its use, but it is comforting. The wound is closed in the usual manner, the drain coming out through the incision or through a separate stab wound as desired.

The aftercare is more or less routine except that the rubber drain is left undisturbed for about seven days and then is withdrawn 2 inches a day, being out on the tenth or the eleventh day. Some bile-stained mucoid material usually drains out. The patient may be ambulant early or late as the individual case indicates.

Fig. 8—All redundant wall excised.

Fig. 9—Sutures inserted around cut edge. Mucosa to be fulgurated.

POSSIBLE DANGERS

The possible dangers are as follows :

(1) Attempting to remove too much of the upper part of the wall of the gall-bladder in an effort to make this operation resemble the standard cholecystectomy, consequently entering the danger area, and imperilling the ducts and vessels. A generous portion of the wall should be left as a protective shield.

(2) By the too liberal use of phenol or by using too powerful a current when coagulating the mucosa and so damaging adjacent structures. These are only possibilities to be considered.

(3) Secondary hæmorrhage due to sloughing along the edge of the gall-bladder wall and involving branches of the cystic artery. In this series this has not happened, but I have always felt this to be a distinct possibility.

(4) Damage to an abnormal cystic artery with hæmorrhage in those cases where the cystic artery arises from the hepatic artery low down or from the gastroduodenal artery and enters the gall-bladder from its under surface—i.e., in the region of Hartmann's pouch. This should not give any trouble, because it will be clamped with the forceps applied to the wall before it is cut away.

(5) Persistent mucous fistula. Careful attention to cauterising the mucosa will prevent this.

(6) Persistent biliary fistula. Theoretically one would expect this to develop at times, but in this series it has not. Perhaps the cauterisation of the duct effectively seals it off.

None of the above complications has been observed in the 23 cases. On the contrary, all the cases have been singularly free from any trouble. Still, I think these and other possible dangers should always be in one's mind when using this method.

SUMMARY AND CONCLUSIONS

A safe method for the removal of a difficult gall-bladder is presented. It is of use in those cases in which, at the time of operation, the gall-bladder is considered too dangerous to remove because of inflammation around the neck, requiring hazardous dissection with attendant hæmorrhage and possible damage to the biliary ducts and vessels.

In seventeen years 23 patients were operated on by this method with no untoward immediate or late postoperative sequelæ.

The method can be used together with exploration of the common duct.

The operation is not to be confused with the cauterisation method advocated by Pribram (1939) and others. Its principle is entirely different: all the surgical manoeuvres are confined to an area clearly visible at all times, and no attempt is made to dissect out the vessels and duct at the neck. On the contrary, one tries to keep as far away as possible from these structures. By working from within the cavity of the gall-bladder they are at all times protected by that portion of the wall left in situ.

The operation is not difficult and will probably appeal but little to some surgeons, but it may be of use to those who suddenly find themselves confronted with a situation which appears to be beyond their skill to solve at one stage.

I believe that damage will not be inflicted on the ducts or vessels when using this method, provided that

a portion of the gall-bladder wall is left as a protection and that no dissection is done in the vicinity of these structures.

I am indebted to Dr. H. M. Edmison, of Victoria, B.C., for the diagrams.

KERNICTERUS FOLLOWING EXCHANGE TRANSFUSION

D. A. MCGREAL

M.B. St. And., M.R.C.P., D.C.H.

SENIOR REGISTRAR, DEPARTMENT OF CHILD HEALTH,
 MEDICAL SCHOOL, DUNDEE

A TRIALS committee of the Medical Research Council is at present considering the indications for, and the results of, treatment of hæmolytic disease of the newborn. A preliminary report (Mollison and Walker 1952) shows that the use of exchange transfusion has greatly reduced the incidence of kernicterus: of 62 infants treated in this way 4 developed kernicterus, 3 of them being premature babies. A similar improvement has occurred in the U.S.A. with the use of exchange transfusions: "It seems entirely probable that kernicterus can be practically eliminated as a complication of erythroblastosis foetalis" (Allen et al. 1950).

Experience in Dundee in 1952-53 has, however, not been so encouraging. During these two years there were 30 infants with hæmolytic disease of the newborn: 10 were considered to need no treatment, 16 had exchange transfusions, 1 died during exchange transfusion, and 3 had simple transfusions. Kernicterus developed in 5 infants, of whom 4 had had exchange transfusions, 3 of these 4 being premature babies.

2 cases of kernicterus following exchange transfusion also occurred in 1950-51. Both infants were mature, the birth-weights being 6 lb. 5 oz. (cord-blood Hb 12.6 g. per 100 ml.) and 7 lb. 13 oz. (cord-blood Hb 11.2 g. per 100 ml.). Both received exchange transfusions shortly after birth, packed cells being used. The 1st child was seen at the age of 1 year and 9 months and showed severe choreo-athetosis; the 2nd died on the third day, and kernicterus was found at necropsy. These 2 cases are mentioned because the infants were mature, and because packed cells were used for the replacement transfusions; they will not be considered further here.

Case-records

Case 1.—A boy weighing 5 lb. 1 oz. was born after normal pregnancy and labour at home. The mother's blood was not examined before the birth. This pregnancy was the mother's sixth. The fifth baby became jaundiced shortly after birth but was not treated; the others were apparently unaffected. When jaundice developed in case 1 a few hours after birth, he was transferred to hospital, where the direct Coombs test was found to be positive, the blood group-A Rh-positive, and the capillary blood Hb 19.6 g. per 100 ml.

Exchange transfusion with group-A Rh-negative blood, seven days old, was given twenty hours after birth, 350 ml. of blood being exchanged. Later the same day the capillary-blood Hb was only 9.6 g. per 100 ml.; so a simple transfusion of 80 ml. of group-A Rh-negative blood was given. The jaundice, which was then considerable, increased steadily during the next two days. On the third day the capillary Hb was 16.8 g. per 100 ml. On the fourth day the infant developed head retraction, hypertonicity of limbs, inability to suck, and a cerebral cry. These signs gradually improved during the next few weeks, but at the age of sixteen months the limbs were hypertonic and the baby could not hold up his head or sit up.

He was alert and did not appear to be frankly mentally defective, but he was abnormally restless. There was no sign of deafness.

Case 2.—A boy weighing 4 lb. 10 oz. was born of a normal pregnancy by spontaneous breech delivery with difficulty, but there were no clinical signs of asphyxia. The mother's blood was group-AB Rh-negative and contained antibodies. This was her third pregnancy, and the second baby had been affected and treated by exchange transfusion. The direct Coombs test on the cord blood was positive, the baby's blood being group-A Rh-positive and his liver and spleen slightly enlarged. His cord-blood Hb was 10 g. per 100 ml.

Exchange transfusion with group-A Rh-negative blood, nine days old, was given one and a quarter hours after birth, 309 ml. of blood being removed and 332 ml. injected. The transfusion was well tolerated, and the capillary-blood Hb twelve hours later was 18.2 g. per 100 ml. During the second and third days the jaundice deepened, but there were no symptoms and the Hb was 16.8 g. per 100 ml. Early on the fourth day there was a sudden onset of cyanosis, head retraction, and inability to suck. The infant appeared collapsed and, though there was temporary improvement with resuscitation, terminal hæmorrhagic phenomena developed six hours after the onset, and the baby died. Necropsy showed yellow staining of the nuclei in the medulla and of the periventricular white matter

Case 3.—A girl weighing 5 lb. was born of a normal pregnancy and labour, but the mother's blood was group-AB Rh-negative and contained antibodies. Her only previous pregnancy had produced an unaffected infant. The direct Coombs test on the cord blood was positive, the baby's blood being group-A Rh-positive and the cord-blood Hb 15.4 g. per 100 ml.

Exchange transfusion was given one and a half hours after birth with group-O Rh-negative blood, fourteen days old, 336 ml. being removed and 390 ml. injected. The baby collapsed at the end of the transfusion but recovered quickly with resuscitation, including the removal of 20 ml. of blood. Next day the jaundice deepened and the capillary-blood Hb was 11.2 g. per 100 ml. On the third day there was a sudden onset of extreme rigidity of the limbs, spine, and neck, a cerebral cry, and failure to suck. Shortly afterwards rhythmic and athetoid movements of the upper limbs occurred. During the ensuing week the involuntary movements subsided, the muscle stiffness diminished, and feeding by bottle was resumed. At the age of three weeks no abnormal signs were present, but the capillary-blood Hb was 7.2 g. per 100 ml.; so a simple transfusion of 100 ml. of group-O Rh-negative blood was given. At the age of two months there were no abnormal physical findings.

Case 4.—A boy weighing 6 lb. 4 oz. was born of normal pregnancy and labour. The mother's blood was group-A Rh-negative and contained antibodies. This was her ninth child, the eighth child having died at the age of four days from severe icterus gravis. One of twins resulting from the fourth pregnancy also had icterus gravis. The direct Coombs test on the cord blood was positive, the baby's blood being group-A Rh-positive and the cord-blood Hb 14.7 g. per 100 ml.

Exchange transfusion was given one and a quarter hours after birth with group-A Rh-negative blood two days old, 440 ml. being removed and 480 ml. injected. During the next three days there were no symptoms, but jaundice slowly deepened, and on the third day the serum-bilirubin level was 17 mg. per 100 ml. On the fourth day, with capillary Hb 20.6 g. per 100 ml. and serum-bilirubin level 25 mg. per 100 ml., the baby developed head retraction and inability to suck, followed by hypertonicity of limbs and athetoid movements. The involuntary movements ceased after a further twenty-four hours, but head retraction persisted for three days. On the fourth day after the appearance of abnormal neurological signs bottle-feeding was resumed, and the baby went home at the age of twelve days, with capillary Hb 20.6 g. per 100 ml.

Readmission.—He was readmitted to hospital at the age of seven weeks because of increasing pallor and frequent epistaxes. Investigations showed that the serum-bilirubin level was 1.75 mg. per 100 ml., prothrombin-time normal, thymol turbidity 2 units, cephalin flocculation negative, alkaline phosphatase 55 King-Armstrong units %, and plasma-protein level 5.2 g. per 100 ml. (albumin 3.5 g. per 100 ml., globulin 1.7 g. per 100 ml.). No abnormal neurological signs were present, and the baby was transferred to another hospital, nearer his home, but he died. The necropsy

findings are not yet available; the brain was not sectioned before fixation.

Discussion

In cases 1-4 the onset of abnormal cerebral signs was preceded by steadily increasing jaundice, but only in case 4 were repeated estimations made of the serum-bilirubin level, and in this case, at the time of symptoms, the level was 25 mg. per 100 ml. The diagnosis was confirmed at necropsy in case 2, but in cases 1, 3, and 4 it rested on the clinical findings. It is generally agreed, however, that the clinical features are usually adequate for diagnosis, though the increased liability of these infants to intracranial hæmorrhage must be borne in mind.

Indications for Exchange Transfusion.—We accept the following criteria of the need for exchange transfusion: (1) an affected baby weighing at birth $5\frac{1}{2}$ lb. or less; (2) an affected baby weighing at birth more than $5\frac{1}{2}$ lb. but with cord-blood Hb less than 14.8 g. per 100 ml.; and (3) an affected baby weighing at birth more than $5\frac{1}{2}$ lb. and having cord-blood Hb more than 14.8 g. per 100 ml., but with a bad family history—i.e., a previously severely affected sibling. These criteria correspond fairly well to those suggested as desirable by Mollison and Walker (1952). However, the amount of cord Hb may not truly indicate the severity or rapidity of the hæmolytic process, and recent work by Walker and Turnbull (1953) suggests that a high level may be a reflection, in part, of intra-uterine anoxia, and the risk of cerebral damage may be greater in such cases.

Length of Storage of Blood.—It is well known that, with prolonged storage, potassium and phosphate pass from the red cells to the plasma, and that after fourteen days' storage the plasma-potassium levels may rise considerably (up to 70 mg. per 100 ml.). Since the newborn baby may already have a high plasma-potassium level (up to 30 mg. per 100 ml.) toxic levels may be reached during exchange transfusion. In case 3 the transfused blood was fourteen days old, and the infant developed cardiac insufficiency at the end of the transfusion. Since this baby had not shown much anæmia at birth (cord Hb 15.4 g. per 100 ml.), hyperkalæmia may have developed. This is not known to affect the incidence of kernicterus, but the possibility of its occurrence does call for care in transfusion. If there is no alternative to using stored blood over seven days old, the amount of calcium gluconate injected should be increased and the rate of transfusion slowed.

Amount of Blood Exchanged.—It is usually considered that an amount corresponding to 70 ml. per lb. of body-weight is adequate. In cases 1-4 the average amount was 75 ml. per lb. Only in case 4 were packed cells used; in the other cases whole blood was transfused. American workers have said that the use of packed cells is not only unnecessary but also contra-indicated (Hsia et al. 1952a), because the transfused cells may undergo more rapid hæmolysis and raise the serum-bilirubin level unduly. Further, it is pointed out that the object of the exchange is to remove circulating antibodies and blood pigment in addition to supplying red cells, and that whole blood is the best medium for this.

Serum-bilirubin Level.—This has been estimated regularly only in case 4. Hsia et al. (1952b) have shown that a direct correlation exists between the height of the serum-bilirubin level and the development of kernicterus; with levels over 31 mg. per 100 ml. 50% of cases became affected, and with levels of 16-30 mg. per 100 ml. 18% were affected. The routine estimation of serum-bilirubin levels on small ill babies is unfortunately a difficult procedure. A micro-technique such as has been developed by Hsia et al. (1952c) in Boston would help greatly, but is not suitable for routine laboratory use. Another difficulty is to fix an arbitrary level of serum-bilirubin above which exchange transfusion is indicated.

Blood-sugar.—Although Gerrard (1952) has suggested that hypoglycæmia may contribute to the production of kernicterus, the normal standards for blood-sugar levels in newborn infants are not sufficiently defined to warrant interference with much hope of improvement. However, the question remains open.

Ætiology of Kernicterus.—The following theory regarding the pathogenesis of kernicterus is perhaps most acceptable at present:

(1) *Increased serum-bilirubin level:* Küster and Krings (1950) have shown, in the case of the young rabbit, that bilirubin, when present in sufficient concentration and for a sufficient length of time, is toxic to nerve tissue. A similar mechanism may operate in man, and Claireaux et al. (1953) believe that the pigment involved in kernicterus is indirect-reacting bilirubin.

(2) *Increased vascular permeability in hæmolytic babies and non-hæmolytic premature babies:* in this connection Morison (1952) writes of hæmolytic babies "this immaturity, and a real but not properly understood structural and functional inferiority of the tissues and organs of the foetus are not sufficiently appreciated." Perhaps, then, a hæmolytic baby should be considered premature when its birth-weight is less than 6½ or 7 lb. instead of the accepted 5½ lb.

Treatment.—If the principal factor is bilirubin, treatment should logically be directed towards lowering the serum-bilirubin level by repeated exchange transfusions. This has been done in America (Hsia et al. 1952a), the aim being to keep the level below 20 mg. per 100 ml., and the results appear to have been satisfactory. However, it must be remembered that exchange transfusion carries a risk, and that the success of repeated exchanges depends a great deal on the operator. Perhaps, too, a rapid rise in serum-bilirubin level is as likely to cause kernicterus as is a moderate persisting level. Abelson (1953) reports 2 cases in which exchange transfusion was given at the onset of abnormal neurological signs, with apparent recovery and freedom from residual disability. In one case the exchange was the first, and in the other the second. If this could be confirmed, treatment would be simplified, but from the discussion reported (Hsia et al. 1952a) it appears that confirmation is lacking. It seems probable that, until we know more about the ætiology of kernicterus, a small proportion of cases of hæmolytic disease will continue to develop kernicterus despite all therapeutic efforts, but that, in the meantime, keeping the serum-bilirubin as low as possible by repeated exchange transfusion offers the best hope of reducing the incidence.

Summary

4 cases of kernicterus have occurred in 16 infants treated by exchange transfusion for hæmolytic disease of the newborn. 3 of the cases were in premature infants.

2 additional cases, both in mature infants, are briefly reported.

Possible factors bearing on the production of kernicterus are discussed.

The use of repeated exchange transfusions to keep the serum-bilirubin levels low is mentioned.

My thanks are due to Prof. J. L. Henderson for his constant help and encouragement in the preparation of this paper; to Dr. J. Thomson for permission to publish case 4; and to Dr. J. D. Andrew for giving the exchange transfusion in case 4.

INTRASPLENIC PRESSURE AS INDEX OF PORTAL VENOUS PRESSURE

MICHAEL ATKINSON

M.D. Lond., M.R.C.P.

MEDICAL REGISTRAR AND TUTOR

SHEILA SHERLOCK

M.D. Edin., F.R.C.P.

PHYSICIAN AND LECTURER

POSTGRADUATE MEDICAL SCHOOL OF LONDON

THE spleen is largely composed of red pulp, which communicates freely with the intrasplenic portal venous radicles (fig. 1). It therefore seemed possible that the pulp pressure might be related to the portal venous pressure. The introduction of a safe method of percutaneous trans-splenic portal venography (Dreyer and Budtz-Olsen 1952, Bahnson et al. 1953, Walker et al. 1953) for the investigation of portal hypertension provided an opportunity of measuring the intrasplenic pressure through the needle used for injection of the contrast medium. Intrasplenic pressure has been measured by this technique and its validity as an index of portal venous pressure assessed. Results have been correlated with the portal venous pressure measured by occluding the hepatic vein (Paton et al. 1953) and directly at operation.

Methods

Intrasplenic pressure was measured in 28 patients with splenomegaly and suspected disease of either the liver or the portal vein, all of whom had a normal plasma-prothrombin time and blood-platelet count. They were placed recumbent with the left hand behind the head. A site was chosen in either the 8th or the 9th intercostal space in the mid-axillary line, and local anaesthesia was induced with 2% procaine solution down to and including the capsule of the spleen. A fine lumbar-puncture needle 7 cm. long, of outer diameter 0.7 mm., was inserted in a cephalad direction at an angle of 45° to the transverse plane. If the spleen was greatly enlarged below the costal margin, the needle was inserted subcostally directly into its outer surface. Resistance was met when the spleen was reached, and thereafter the patient was asked to breathe quietly. After penetrating 2 cm. into the spleen the stylet was removed, when blood could be seen dripping slowly from the needle. This was found to be a most valuable indication that the needle was in the correct position. The swing of the needle with respiration was

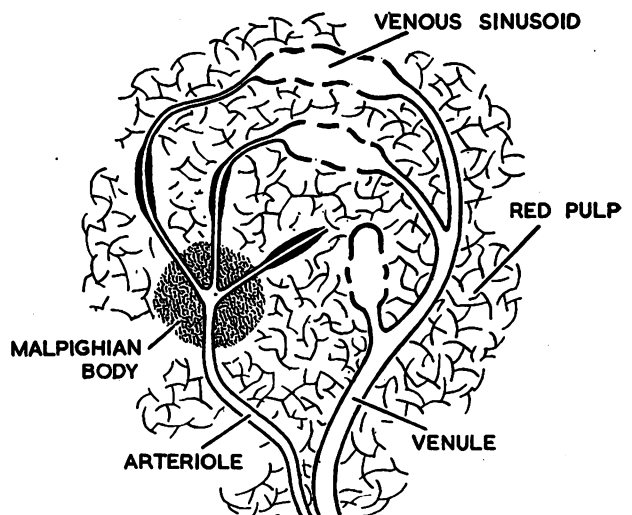

Fig. 1.—Diagram of circulation in spleen (modified after McNee 1931), showing free communication between red pulp and tributaries of portal vein in the spleen.

not in any way restricted. The needle was connected with a strain gauge by a length of 'Polythene' tubing, and the pressure was recorded with the patient breathing quietly. The zero level was taken at a point 5 cm. below the sternal angle with the patient supine. In every instance the position of the needle in the spleen was confirmed by subsequent injection of contrast material for trans-splenic portal venography. The needle remained in the spleen for only 30 seconds, the time taken for the two procedures.

In 12 patients, after the initial pressure had been recorded, the needle was advanced a further 5 mm.; in this way pressures were obtained from two or three different positions in the spleen.

Intrasplenic pressure was measured directly at operation in 7 patients undergoing gastrectomy and compared with pressures obtained at the same time from a main portal venous tributary. These patients had spleens

TABLE I—AGREEMENT OF PRESSURES TAKEN FROM DIFFERENT PARTS OF SAME SPLEEN

Case no.	Pressure in different parts of spleen (mm. Hg)			Range of variation (mm. Hg)
	1	2	3	
1	5	5	4	1
2	6	6	6	0
3	4	6	8	4
4	9	10	9	1
5	10	10	10	0
6	15	10	12	5
7	12	14	..	2
8	17	12	14	5
9	15	15	19	4
10	19	21	..	2
11	24	21	..	3
12	25	20	20	5

of normal size and no evidence of portal venous hypertension.

In 22 patients the pressure obtained by occluding an hepatic vein was measured at a later date by catheterisation of the hepatic vein. This pressure is a measure of the intrasinusoidal pressure and therefore of the portal venous pressure (Paton et al. 1953).

Results

Safety

There were no complications and in particular no clinical evidence of intraperitoneal bleeding, but it must be emphasised that a fine needle was used and deep respiration was avoided. Puncture of the spleen at laparotomy enabled inspection of the puncture site, and the blood-loss never exceeded a few ml. Review of the published reports has revealed only transient side-effects of percutaneous trans-splenic venography, and no death has been reported (Atkinson et al. 1954).

Variation of Pressure in Same Spleen

The pressure tracing obtained was steady without pulsations. The respiratory variation with quiet breathing did not exceed 2 mm. Hg.

It is possible that the needle may occasionally enter a large artery instead of the red pulp and give a falsely high pressure. This happened only once in 75 readings and was confirmed by prominent pulsations on the tracing. This difficulty is prevented if in every instance two readings are taken in the spleen by advancing the needle a further 5 mm. after the first recording.

The intrasplenic pressure varied little from place to place in the same spleen (table I).

Results in Patients without Portal Hypertension

The intrasplenic pressure was measured in 14 patients without portal hypertension. 7 with normal spleens were studied at the time of laparotomy and 7 with splenomegaly during portal venography (table II). The pressure varied between 3 and 17 mm. Hg, and this has been taken as the range of normal.

TABLE II—SUMMARY OF RESULTS

Condition	No. of patients	Mean intrasplenic pressure (mm. Hg)	Range (mm. Hg)
Portal cirrhosis ..	11	25.5	17-35
Biliary cirrhosis ..	5	22.6	17-28
Extrahepatic obstruction of portal vein ..	5	24.4	20-29
Other patients : Normal spleen ..	7 } 14	10.3 } 10.0	3-17
Large spleen ..	7	9.7	

The pressure did not differ significantly between the 7 patients with spleens of normal size and the 7 with splenomegaly (table II). The size of the spleen therefore does not influence intrasplenic pressure.

Results in Portal Hypertension

The 11 patients with portal cirrhosis all showed an intrasplenic pressure greater than the upper limit of that found in the group without portal hypertension (table II). The mean value was 2½ times that seen in the latter group.

The intrasplenic pressure was surprisingly high in the 5 patients with biliary cirrhosis. These patients, however, also showed a high portal venous pressure when it was measured by catheterisation of the hepatic vein.

Each of the 5 patients with extrahepatic obstruction of the portal vein had a high intrasplenic pressure.

Correlation of Intrasplenic Pressure with Estimated Portal Venous Pressure

In the 24 patients studied there was a statistically significant linear correlation between the intrasplenic pressure and the estimated portal venous pressure whether measured by occlusion of an hepatic vein or directly at operation (fig. 2). If the intrasplenic pressure is measured, it is possible to predict the portal venous pressure within 8 mm. Hg with a 95% degree of accuracy. The intrasplenic pressure exceeds the estimated portal venous pressure by 2-6 mm. Hg, the higher the pressure the greater the difference.

Extrahepatic Portal Venous Obstruction

In these patients the obstruction to the portal vein is extrahepatic, and the intrahepatic portal venous pressure is not raised. The pressure obtained by occluding an hepatic vein is therefore normal, and this finding,

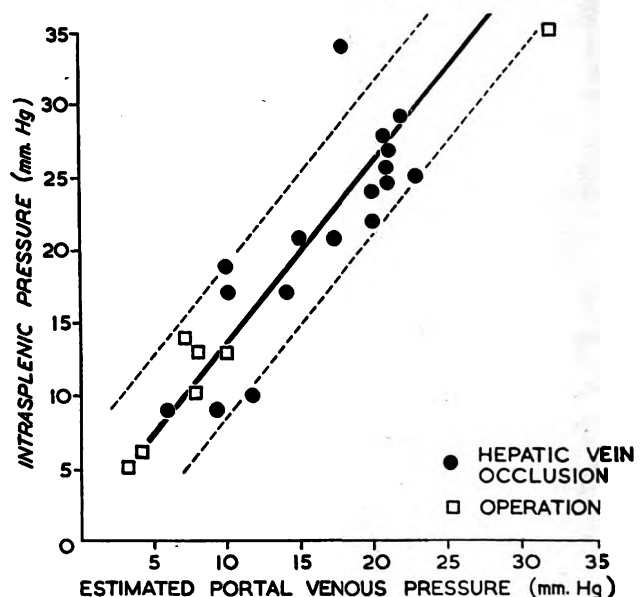

Fig. 2—Correlation of Intrasplenic pressure with estimated portal venous pressure: solid circles, by occlusion of an hepatic vein; squares, at operation. Interrupted lines represent limits of 95% confidence.

in conjunction with a raised intrasplenic pressure, strongly suggests extrahepatic portal venous obstruction (fig. 3).

Case-report

A boy, aged 17, presented with gastro-intestinal bleeding. Four years previously he had had acute appendicitis complicated by pylophlebitis and liver abscesses. Splenomegaly was now the only abnormal clinical finding. Liver-function tests showed no evidence of hepatocellular damage, and aspiration hepatic biopsy revealed normal histology. Varices were not seen radiologically after a barium swallow. The intrasplenic pressure was raised (29 mm. Hg), but the pressure obtained by occluding an hepatic vein was normal (12 mm. Hg). These findings suggested that the portal vein was occluded as a result of the old infection, and this was confirmed by trans-splenic portal venography, which showed

Fig. 3—Extrahepatic obstruction of portal vein.

compression of the portal vein within the liver, presumably by scar tissue.

Similar findings were observed in 4 other patients with extrahepatic portal venous obstruction which in every instance was confirmed by portal venography (table III).

Discussion

The tip of a needle introduced into the spleen will probably lie in the splenic pulp, which forms the great mass of the organ. Anatomically the pulp is in free communication with the splenic venules; therefore it is not surprising that intrasplenic pressure bears a close relation to the portal venous pressure measured directly or by occluding an hepatic vein. The intrasplenic pressure is slightly higher than the portal venous pressure, as would be expected from the direction of flow in the portal system.

A rise in intra-abdominal pressure will increase the portal venous pressure and will be reflected in both intrasplenic pressure and the pressure obtained by occluding an hepatic vein. Patients with tense ascites were not included in this series; high pressures on occlusion of an hepatic vein, however, are found in such patients, and a rise in the intrasplenic pressure would be expected. Contraction of the muscles of the abdominal wall will raise the intra-abdominal pressure, the portal venous pressure, and the intrasplenic pressure by not more than 2 mm. Hg.

Intrasplenic puncture is as safe as, and much simpler than, other current methods of determining the pressure in the portal venous system—e.g., catheterisation of an hepatic vein, puncture of oesophageal varices during oesophagoscopy (Allison 1951), and directly by puncture of a portal venous radicle at operation. It is simpler and can be done more frequently than transsplenic portal venography.

The technique has many practical clinical applications. It may be used to confirm the diagnosis and to assess

TABLE III—ASSOCIATION BETWEEN PRESSURE OBTAINED BY OCCLUDING HEPATIC VEIN AND INTRASPLENIC PRESSURE IN EXTRAHEPATIC OBSTRUCTION OF PORTAL VEIN

Diagnosis	Age (yr.)	Sex	Pressure obtained by occluding hepatic vein (mm. Hg) (normal range 2-12)	Intrasplenic pressure (mm. Hg) (normal range 3-17)
Obstruction of portal vein by scar tissue	17	M	12	29
Portal cirrhosis and thrombosis of portal vein	49	F	7	25
Portal cirrhosis and thrombosis of portal vein	56	F	11	24
Portal cirrhosis and thrombosis of portal vein	59	M	10	20
Biliary cirrhosis and thrombosis of portal vein	41	F	7	24

the severity of portal hypertension in the patient with liver disease. It is useful in following fluctuations in the portal venous pressure during the course of cirrhosis of the liver. Measurements of intrasplenic pressure provide a convenient base-line before operations are undertaken to relieve portal venous hypertension, and may be repeated postoperatively as an indication of the efficacy of the operation. A rise in intrasplenic pressure after the operation of portacaval anastomosis, for instance, would strongly suggest closure of the venous shunt.

The intrasplenic pressure can conveniently be measured in the medical ward without simultaneous trans-splenic venography, and may be useful in elucidating the cause of undiagnosed splenomegaly. It may prove of value in the investigation of the cause of gastro-intestinal bleeding in association with splenomegaly. It should not be done until the bleeding has ceased.

Used in conjunction with catheterisation of an hepatic vein the method is useful for the diagnosis of obstruction of the portal vein.

Summary

Percutaneous splenic puncture with a fine needle is a simple and safe method of estimating the portal venous pressure. The intrasplenic pressure varies little throughout the spleen and is uninfluenced by the size of the spleen. It bears a linear relationship to the portal venous pressure estimated by other methods.

In 14 patients without portal hypertension the intrasplenic pressure was 3-17 mm. Hg, with a mean of 10 mm. Hg. In 11 patients with portal cirrhosis the mean intrasplenic pressure was 25.5 mm. Hg, in 5 patients with biliary cirrhosis 22.6 mm. Hg, and in 5 patients with extrahepatic portal vein obstruction 24.4 mm. Hg.

The value of this technique in the diagnosis and management of portal hypertension is discussed.

We are indebted to Mr. M. R. Ewing, F.R.C.S., for his cooperation; Dr. N. F. Coghill, Dr. E. D. H. Cowen, Dr. P. Gibson, Dr. J. D. Paultett, and Dr. J. D. Whiteside for kindly referring patients; Mr. J. I. MacNaughton and Mr. B. Rowe for technical assistance; and the Lund Fund of the Diabetic Association for an expenses grant.

ADDENDUM

Since this paper was written, we have observed that in one patient intrasplenic pressure fell from 35 to 18 mm. Hg after successful construction of a portacaval anastomosis, and in one other patient repair of a stricture of the common bile-duct resulted in a fall in intrasplenic pressure from 28 to 12 mm. Hg one year later.

Preliminary Communication

HOMOLOGOUS SERUM JAUNDICE AFTER TRANSFUSION OF WHOLE BLOOD, DRIED SMALL-POOL PLASMA, DRIED IRRADIATED PLASMA, AND KAOLIN-TREATED FILTERED LIQUID PLASMA*

FOR more than a decade homologous serum jaundice has been recognised as a delayed complication of transfusion of blood and plasma. The highest incidence has been observed after the use of large-pool plasma or serum—i.e., plasma or serum prepared from pools containing the plasma of 300 or more donations of blood. In 1946 Spurling et al.,¹ in a survey of 1054 patients who had received such plasma, found that 77 (7.3%) had developed homologous serum jaundice between one and five months after transfusion, whereas no cases were found among 891 recipients of whole blood. Brightman and Korns,² in the United States, observed the complication in 29 (4.5%) of 649 patients given dried plasma (size of pool not specified); 4 of the 29 patients died of hepatic necrosis.

Because of the high incidence of homologous serum jaundice after the transfusion of large-pool plasma, the Medical Research Council decided, in June, 1945, to discontinue the production of large-pool plasma and instead to prepare plasma from small pools in an effort to restrict the dissemination of the infective agent. The latter type of plasma is known as small-pool plasma and is derived from not more than 10 donations of blood.

In 1949 Lehane et al.³ reported the results of a comparative survey of the use of dried large-pool plasma, dried small-pool plasma, and whole blood. These are summarised in table I.

TABLE I—RESULTS REPORTED BY LEHANE ET AL.

Transfusion fluid	No. of patients on whom incidence of jaundice is based	No. developing homologous serum jaundice attributed to transfusion	Deaths attributed to homologous serum jaundice
Whole blood	2772	22 (0.8%)	0
Dried small-pool plasma with or without blood	814	12 (1.47%)	1
Dried large-pool plasma with or without blood	820	100 (12.2%)	6

This survey showed that restriction of the size of plasma pool greatly reduced the incidence of homologous serum

* The surveys reported here were organised and carried out on behalf of the Ministry of Health, Medical Research Council, and the Department of Health for Scotland by an ad-hoc group consisting of: Dr. R. J. DRUMMOND and Mrs. B. F. WILLIAMS, Regional Transfusion Centre, Cardiff; Dr. D. LEHANE and Miss K. DAVIES, Regional Transfusion Centre, Liverpool; Dr. F. STRATTON and Mrs. K. J. COOPER, Regional Transfusion Centre, Manchester; Dr. J. WALLACE and Miss K. J. CLARK, Glasgow and West of Scotland Blood Transfusion Service, Glasgow; Sir ALAN DRURY, F.R.S., Institute of Animal Physiology, Babraham; Dr. W. d'A. MAYCOCK, Lister Institute, Elstree, Herts (consultant adviser to Ministry of Health); Mr. L. VALLET, Lister Institute, London, S.W.1; and Dr. J. T. BOYD, Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

jaundice, and that the risk of this complication after dried small-pool plasma was little greater than that attaching to whole blood.

The observations of Oliphant and Hollaender⁴ in 1946 and Wolf et al.⁵ in 1947 had suggested that irradiation with ultraviolet light would inactivate the infective agent. Blanchard et al.,⁶ using a known icterogenic pool of serum, reported in 1948 that, of a group of 15 volunteers, 3 developed hepatitis with jaundice, 1 hepatitis without jaundice, and 3 had presumptive hepatitis. Of 11 volunteers who received plasma from

TABLE II—INCIDENCE OF JAUNDICE AFTER TRANSFUSION OF BLOOD, OF SMALL-POOL PLASMA, AND OF IRRADIATED LARGE-POOL PLASMA

Transfusion fluid	No. of patients on whom incidence of jaundice is based	No. developing jaundice of doubtful aetiology	No. developing homologous serum jaundice attributed to transfusion	Deaths attributed to homologous serum jaundice
Blood	2538	4	4 (0.16%)	0
Dried small-pool plasma with or without blood	867	0	1 (0.12%)	0
Dried irradiated large-pool plasma with or without blood	984	5	39 (3.96%)	1

the same pool which had been irradiated, none showed any evidence of hepatitis. In the light of these results, "Minimum Requirements" of the U.S. National Institutes of Health, issued early in 1949, made the ultraviolet irradiation of plasma obligatory.† In 1950 reports of homologous serum jaundice after the transfusion of irradiated plasma appeared in the United States (James et al.,⁷ Rosenthal et al.,⁸ Barnett et al.⁹) but insufficient data were given to allow any assessment to be made of the incidence of this complication.

Since irradiation with ultraviolet light under suitable conditions appeared to eliminate or at least reduce the risk of homologous serum jaundice, it was important to discover whether irradiated plasma in fact carried a smaller risk than small-pool plasma. The Ministry of Health and Medical Research Council therefore decided that plasma should be irradiated under carefully controlled conditions and that surveys should be made in the areas of three regional hospital boards (Cardiff, Liverpool, and Manchester) with the object of comparing the incidence of homologous serum jaundice after dried irradiated plasma with that (a) after dried unirradiated small-pool plasma, prepared concurrently by the usual methods in use since 1945, and (b) after whole blood alone. In these surveys each member of the population at risk was followed-up in a manner similar to that described by Spurling et al.¹ and Lehane et al.³ The surveys were carried out during the period January, 1952, to June, 1953.

The plasma was irradiated in an apparatus designed on the Habel-Sockrider principle (Habel and Sockrider¹⁰) using a flow-rate of 5 litres per hour with an ultraviolet emission

† Irradiation is still obligatory; it is now regarded as a means of maintaining the bacterial sterility of plasma.

of 5.5 watts at 2537 Å. Voltage supply to the ultraviolet lamps, rate of flow, and other physical conditions were held constant during each "run." 15-litre pools from approximately 60-80 donors were first prepared from the 10-donor pools, and these larger pools were filtered and run through the irradiator in continuous sequence. The plasma from 600-800-donor pools was irradiated in this way during one "run." These operating conditions caused no significant changes in protein detectable by electrophoretic analysis.

The combined results of these three surveys are summarised in table II.

A fourth survey, arranged by the Department of Health for Scotland on the advice of the Advisory Committee on Medical Research and with the coöperation of the Scottish National Blood Transfusion Association, was organised in the same way as the English surveys and made in the Glasgow area during the period June, 1951, to August, 1953, to compare the incidence of homologous serum jaundice after kaolin-treated filtered liquid plasma (Maizels¹¹) with that after whole blood alone. The liquid plasma was kept at room-temperature for varying periods of time; it was never "younger" than three weeks, and some was over twelve months old when transfused. Storage of plasma at room-temperature has been advocated by Allen et al.^{12, 13} as a means of inactivating the agent in plasma responsible for homologous serum jaundice. The maximum size of pools was derived from 140 donations of blood, seven 15-20-donor pools being clarified and filtered in continuous sequence. The results of this survey are summarised in table III.

TABLE III—INCIDENCE OF JAUNDICE AFTER TRANSFUSION OF BLOOD AND OF KAOLIN-TREATED PLASMA

Transfusion fluid	No. of patients on whom incidence of jaundice is based	No. developing jaundice of doubtful aetiology	No. developing homologous serum jaundice attributed to transfusion	Deaths attributed to homologous serum jaundice
Blood	1387	3	5 (0.36%)	0
Kaolin-treated filtered liquid plasma ..	1366	8	16 (1.17%)	0

GENERAL CONCLUSIONS

1. It is apparent that the exposure of plasma to ultraviolet light under the conditions used did not inactivate the causative agent of homologous serum jaundice.

2. The incidence of homologous serum jaundice after transfusion of the dried small-pool plasma is very low and does not differ significantly from that found after transfusion of whole blood; both are less than that found by Lehane et al.³

3. The incidence of homologous serum jaundice observed after kaolin-treated filtered liquid plasma was slightly smaller than that reported after dried small-pool plasma by Lehane et al.³ but greater than that after dried small-pool plasma in the present English surveys. One of the cases of jaundice occurred after the transfusion of plasma ten months old, and another after plasma seven months old, which had been stored at room-temperature.

Full details of these surveys will be published elsewhere.

Reviews of Books

Progress in Clinical Surgery

Editor: RODNEY SMITH, M.S., F.R.C.S., surgeon, St. George's Hospital. London: J. & A. Churchill. 1954. Pp. 414. 36s.

THE young surgeon seeking helpful instruction on those developments in clinical surgery which are too recent to be found in the textbooks is often faced with dogmatic but contradictory opinions which he must evaluate as best he can. Most of the original articles in medical periodicals are one-sided, and many postgraduate lectures are no less an expression of personal opinion. What the young surgeon needs is a balanced assessment of opposing views on controversial matters, with the arguments for and against fairly stated.

This symposium, by 20 well-established but not too senior surgeons, has been produced with the avowed purpose of helping "the postgraduate student working for his final F.R.C.S. examination and the younger surgeon with a recent hospital appointment," and it serves this purpose admirably. In comparatively short space most of what the postgraduate student requires to add to his textbook studies is condensed in highly readable form; and this is achieved without exclusion of the more specialised branches of surgery. There has inevitably been considerable selection of material but few will quarrel with the choice. The only omission calling for comment is that the otherwise excellent chapter on brain surgery contains no reference to tentorial impaction; but some will regret that the chapter on cancer of the mouth and pharynx has not the same impartiality as the rest of the work.

The book can be confidently recommended not only for the young surgeon but for more senior surgeons who find themselves unable to keep pace with the journals.

Plague

R. POLLITZER, M.D., formerly of the division of epidemiological and health statistical services, World Health Organisation. Geneva: W.H.O. Monograph Series no. 22. H.M. Stationery Office. 1954. Pp. 698. £3 5s.

WE have long been waiting for an authoritative and comprehensive textbook on plague, and here it is. Dr. Pollitzer was a co-author of a classical manual on plague published in 1936 and has spent his time since then continuing the struggle against plague in China. (An example of his scientific indifference to the wars and political upheavals going on around him was his arrest, when working with a League of Nations anti-epidemic team, for taking a photograph of entomological interest which unfortunately included a battery in action.) His new book is a re-edited compilation of studies published in the *Bulletin of the World Health Organisation* (1951-53) covering every aspect of plague, and it will undoubtedly be the standard textbook for some years to come.

Its ten chapters deal with the history and present distribution; the plague bacillus; immunology; pathology; laboratory diagnosis; hosts; insect vectors; clinical aspects; epidemiology; and control and prevention. It is fully up to date, in that it deals with the sulphonamides and antibiotics in treatment and with the new poisons and persistent insecticides in control. Most of the superb illustrations, particularly those in an annexe on the identification of flea-vectors contributed by F. G. A. M. Smit of the Museum at Tring, have never previously been published.

Those of us who think of plague as a menace of bygone days, or as something which affects the other fellow and not ourselves, will be convinced by a glance at the world maps showing recent human infections in 1952 that this is a parochial view. Even when the control of human plague is successful, the epizootic threat remains, as the insidious spread of rodent plague across the United States has shown. As with yellow fever and tularaemia, watchfulness cannot be relaxed even in non-epidemic countries while the fire smoulders in the woods, since at any time a burning ember may start a conflagration, though modern methods of control and treatment should

limit the outbreak more quickly and with less serious results.

This is exactly the kind of major international scientific work which W.H.O. should sponsor.

Practique de l'hibernothérapie en chirurgie et en médecine

H. LABORIT and P. HUGUENARD. Paris: Masson. 1954. Pp. 256. Fr. 1400.

PAPERS on artificial hibernation began to find their way into the medical press of this country only recently, though the elements of the technique and the use of individual drugs concerned in it have been slowly introduced into clinical practice during the last year or two. Its value cannot yet be assessed, but a controversy has already begun on its merits and potential dangers—even though the pharmacologists are at present unable to offer an account of all the actions of chlorpromazine, the agent chiefly used to produce it.

In this book Dr. Laborit and Dr. Huguénard, the surgeon and anaesthetist who first started the method and popularised the term "artificial hibernation," set out their ten years' experience; and numerous contributors, representing nearly every branch of medicine, add their opinions. Hibernation is recommended for conditions ranging from the treatment of premature babies to cerebral surgery, and from carbon-monoxide poisoning to malignant hypertension. Both theory and practice are dealt with in considerable detail. The complexity of the technique and the polypharmacy that it entails—as many as 15 drugs being used on occasion—will not appeal to many clinicians here, even though there is an apparently rational basis for all that is recommended. Nevertheless, hibernation undoubtedly has value for selected patients, and British workers who have tried it, using a limited number of agents, are mostly enthusiastic. The value of this volume would be greater if the results of hibernation had been compared with those produced by more orthodox methods of anaesthesia or treatment.

Hepatic Circulation and Portal Hypertension

CHARLES G. CHILD, M.D., professor of surgery, Tufts College Medical School. Philadelphia and London: W. B. Saunders. 1954. Pp. 444. 60s.

THE circulation through the mammalian liver is complicated by its dual blood-supply. This introduces many difficulties not only for the student of this circulation but for everyone concerned with hepatic disease. The great importance of the subject, however, has stimulated an enormous volume of research on many animal species, and by divers techniques. It is perhaps hardly necessary to say that the results of such a varied approach have been far from uniform, and often contradictory. The development of the various surgical operations for the relief of portal hypertension, however, has made necessary a better understanding of the problems, and has stimulated Professor Child to collecting into one volume the main contributions to this subject during the past fifty years. A series of six short appendices describe some of the experiments performed by the author and his associates; a seventh deals with the case-histories of patients subjected to various types of shunt operation for portal hypertension.

Students of the liver have long needed a book of this kind, and most of them will wish to thank and congratulate Professor Child. The illustrations are a credit to all concerned.

Preservation and Transplantation of Normal Tissues

A Ciba Foundation Symposium. Editors for the Ciba Foundation: G. E. W. WOLSTENHOLME, O.B.E., M.A., M.B.; MARGARET P. CAMERON, M.A., A.B.L.S. London: J. & A. Churchill. 1954. Pp. 236. 25s.

FROM the clinical viewpoint tissue storage is the provision and storage of spare parts for replacement surgery, and with few exceptions it entails the storage of tissues obtained from other human beings. Since the use of stored tissues is restricted by the fact that some living tissues will not form permanent grafts after transplantation a survey of the problems must take into account the problems of transplantation immunity reactions, leading to death of the graft. Appropriately,

P. B. Medawar's opening contribution to this symposium refers particularly to skin homografts; and later F. K. Sanders describes the difference in behaviour between nerve homografts and nerve autografts. Endocrine homografts are dealt with by P. F. Jones and other contributors. A survey of general surgical problems of tissue transplantation by W. P. Longmire and his associates paves the way for detailed accounts of the surgical application of different tissues, both fresh and preserved, viable or non-viable. Two contributions describe the maintenance and operation of "tissue banks." Other articles of general interest deal with long-term storage of endocrine tissues and skin in a viable state, the preservation of blood, and biophysical aspects of freezing living cells. W. R. Earle describes the maintenance of long-term large-scale tissue cultures; Pomerat and Lewis, methods for the analysis of thermal stress; and P. J. Gaillard the transplantation of cultivated parathyroid tissue in man. This book does full justice to its title.

The Homosexual Outlook

A Subjective Approach. DONALD WEBSTER CORY. London: Peter Nevill. 1953. Pp. 326. 18s.

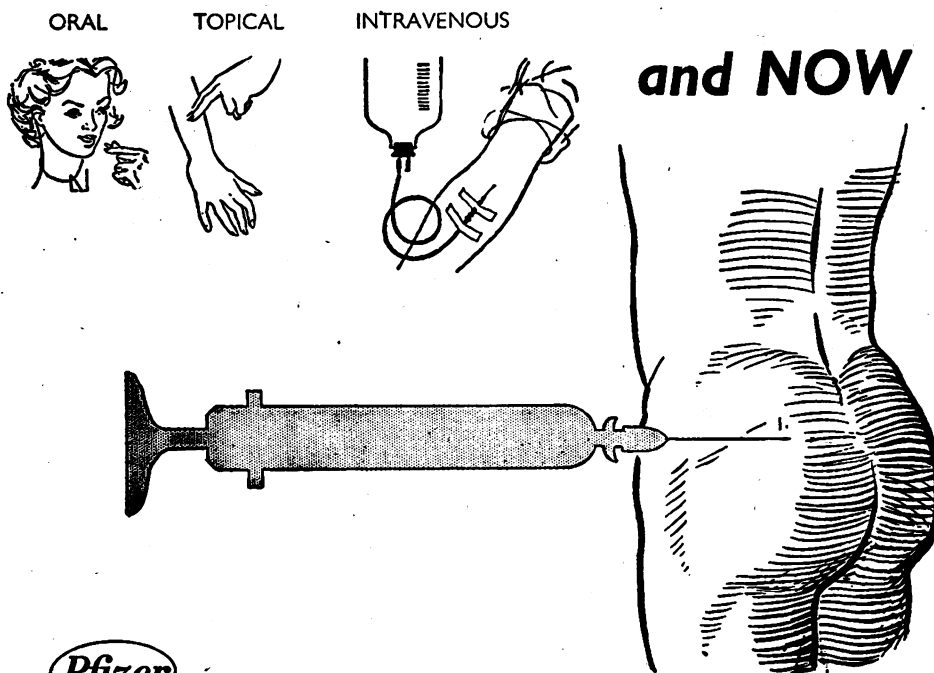

THE author of this book writes sincerely and responsibly about the effect upon his own life of a strong homosexual drive. He describes from direct observation the language and social habits of homosexuals in a large American city, and the personal and social conflicts they must encounter. Of the psychological aspects he gives a review influenced by his reading and his experience of psycho-analysis: he was treated by this method for a long time, and in consequence overcame his feelings of shame and remorse but not his homosexual impulses. He is convinced that psychological treatment cannot change a homosexual into a heterosexual, though it may enable him to marry happily while maintaining a homosexual attachment. Like most educated men and women who are homosexual, the author emphasises the advantages which he believes are conferred by homosexuality, and he names the famous men who are said to have been homosexual (his list includes Francis Bacon, Byron, and Shelley). His argument is, in the main, a plea for a minority—a minority who are, in his view, not so much in need of toleration or therapy as of acceptance and equal treatment, in the light of a reorientation towards sexual life in modern civilisation. He develops this argument with such candour and moral dignity that his book deserves close attention, even though its thesis is repugnant to many.

Pneumoconiosis Abstracts. Vol. 2 (London: Pitman. 1954. Pp. 517. 80s.).—This volume of abstracts, made and compiled by Dr. E. L. Middleton and reprinted from the *Bulletin of Hygiene*, brings us up to 1950. The abstracts are in general clear and precise. The collection is comprehensive and well arranged with a good index, and therefore forms a very valuable reference book; but it is a pity it costs so much.

Basis of Clinical Neurology (3rd ed. London: Baillière, Tindall, & Cox. 1953. Pp. 510. 54s.).—Prof. Samuel Brock's textbook, eight years older since the last edition, maintains its workmanlike tradition. Collaborators have revised sections, and contributed new material, on electro-encephalography, electromyography, electrodiagnostic methods, the visual pathways, cerebral angiography, sensory extinction, and double stimulation; and the whole book reflects the synthesising mind of its editor. As he says in his preface, neurology and psychiatry are drawing nearer to one another; and he believes that one day they will not only be inseparable but will speak the same language.

Medical Progress, 1954: A Review of Medical Progress during 1953 (London: J. & A. Churchill. 1954. Pp. 345. 36s.).—This book, edited by Dr. Morris Fishbein, consists of essays on trends of research in many subjects, including cardiology, surgery, rheumatic diseases, the newer drugs, infectious diseases, gynaecology, reablement, physical medicine, and many other specialties. The contributors, authorities in their fields, make careful and critical surveys of work published during the year, endeavouring to distinguish as far as possible between work making a permanent addition to our knowledge and that which is still experimental; and they provide a guide to rewarding reading in the long bibliographies which end the chapters.

*The first broad-spectrum antibiotic
available for intramuscular injection*

Terramycin

BRAND OF OXYTETRACYCLINE

INTRAMUSCULAR

has been developed for the treatment of infections where parenteral therapy is desirable. This new dosage form completes the range of Terramycin products for oral, topical, intravenous and intramuscular administration.

In severe infections or in those cases where high blood levels are desired, oral or intravenous dosage forms of Terramycin should be used.

DOSAGE of Terramycin intramuscular for Adults is 200-400 mg. per day, administered in divided doses of 100 mg. at six-to-twelve-hour intervals. For children the daily dose is proportionately less. Crystalline Terramycin (Oxytetracycline) Hydrochloride INTRAMUSCULAR is available in single-dose vials of 100 mg.

Full literature is available and will be supplied on request

SENSITIVITY AND COMMON SENSE

Hayfever and allergic rhinitis are often of complex aetiology and tend to persist in spite of the most rigorous treatment. In those cases, however, in which nasal obstruction is the most troublesome symptom, even a measure of relief is welcomed by the patient. Discriminate use of the 'Neophryn'* Spray helps to restore normal nasal function and is probably the best short-term local treatment. Principal advantages are: rapid and prolonged vasoconstriction without secondary congestion, virtual freedom from side-effects, and simple administration by a convenient plastic atomiser.

Basic N.H.S. cost only 2/4

Cortical Localisation

THE extension of neurosurgery beyond the relatively narrow bounds of tumour removal has given strong impetus to investigation into cerebral activity and cortical localisation. The development of psychosurgery, scar excision, topectomy, gyrectomy, and even hemispherectomy,¹ together with electrical stimulation of the brain at operation, have made it possible to apply to human physiology techniques previously restricted to research on animals. Paradoxically (but in keeping with experience in other fields of research) more direct and detailed knowledge has lessened the absolutism of theories on cortical localisation.

Discussing motor representation in the cortex, FULTON² asserted that "the controversy would seem clearly to be one which can be resolved more readily by recourse to experiment than by philosophical reflection." But the information from recent experimental work on the human brain is exceedingly complex and has given rise to argument and counter-argument in abundance; in WALSHE'S³ words, "our knowledge has achieved a high degree of differentiation but yet awaits integration." The trans-oceanic debates of FULTON and WALSHE have been echoed by GOODY⁴ and JEFFERSON.⁵ The details of these controversies are not identical, but in both the main schism relates to the parcellation of the cerebral cortex—to the notion that the cortex is or is not an anatomico-physiological mosaic. There is a spectrum of theories on the subject, at one edge of which are the earlier views of PENFIELD and RASMUSSEN,⁶ whose famous gargoyles epitomise the absolutist concept. Their monumental industry, applied both to the interpretation of epileptic-seizure patterns and to the electrical exploration of five hundred brains, resulted in extremely detailed maps of cortical activity. Lately PENFIELD⁷ has modified his ideas and has declared "that the function of the precentral gyrus is to transmit and no doubt transmute the impulses which reach it from the central integrating system . . . and if a homunculus is drawn it is no more than an aid to memory." At the other end of the spectrum is the view expressed by GOODY and MCKISSOCK⁴ that "there is not a standard brain with all functions set and localised for use. The brain stands ready for training." LASHLEY⁸ emphasised the integrative relation between the "specialised" centres and the rest of the brain, and cast doubt upon the validity of the cyto-architectonic approach to localisation. Further, KALINOWSKY,⁹ reviewing the results of selective cortical ablation, indirectly supports the idea of equipotentiality in asserting that at least in the

prefrontal areas the intensity of the mental change appears to be determined by the quantity of pathways destroyed.

This divergence of views expressed by careful and responsible workers is bewildering. Are they in some way reconcilable? A clue seems to emerge from closer consideration of the techniques employed by the different theorists. It is not really surprising that the cerebral map produced by the histologist differs from that produced by the electrical stimulator: an analogy may be found in the differences between geological and ethnological cartography of the earth's surface. Again, clinical assessment of the diseased brain permits yet another equally valid interpretation of localisation, based on functional deficit. Finally, the results of ablation and of hemispherectomy, viewed against a temporal background in which improvement and even redesign of functional patterns takes place, indicate that there must be some equipotentiality of cerebral tissues. FULTON'S claim for the superiority of experiment to philosophy now seems rather less convincing: it is the interpretation of the integrated experimental results that is so important. In the first place the cyto-architectonic method is clearly valueless in localising function: it requires physiological corroboration. Furthermore, since the effects of strychninisation and of electrical stimulation in no way resemble normal cerebral activity, no firm deduction about localisation of normal function can be made from such techniques. In the face of this experimental confusion it is tempting to resort to clinical pragmatism, but one must beware of the fallacy of identifying the localisation of sign-producing lesions with the localisation of normal function. The apostles of BROCA would be confounded by the recent revelation that ablation of the third frontal gyrus in the dominant hemisphere fails to produce any aphasic symptoms.

Ablation and hemispherectomy may seem to offer means of gaining more precise information. If an area of brain tissue can be removed without disturbing a particular function, it is reasonable to suggest that this function is located elsewhere. The production of gross functional defect by removing a given area of the cortex is powerful prima-facie evidence that the area excised is related to the function lost. But this idea, however attractive, implies that the cerebral cortex is made up of independent nerve-cells, and neglects the complex interweaving of neurones and their dendrites. For if, as seems most probable, cortical function is mediated by interconnected neuronal circuits, ablation can produce its effects by interrupting a particular circuit at a relatively remote point without indicating exactly where function is initiated. Indeed the varying results of topectomy, and the preservation of some motor function after hemispherectomy, can best be explained in terms of variable neuronal patterns, possibly including bilateral connections. Such neuronal patterns could exhibit functional flexibility and allow for some degree of compensatory re-education. This concept in no way involves accepting the view that there is no localisation of function at all—"that all parts of the brain stand ready for training." There seems to be no training of new visual areas, and the residual motor function after hemispherectomy is only a crude parody of the fine movements controlled by an intact brain. Thus the weight of evidence,

which is against a point-by-point localisation of function, nevertheless supports the notion of specialisation of certain cortical areas. We have in fact returned to the doctrine expounded by WALSHE,³ who regards the "hand area" of the motor cortex as a macula of the field of hand movement. This idea is based on the earlier thesis of HUGHLINGS JACKSON¹⁰ that the arm centre represents movements of all parts of the body, but particularly of the arm itself. Such a view would account for certain apparent contradictions in clinical interpretations of cortical localisation—particularly in relation to complex sensory auræ which appear to transgress the classical boundaries of sensory representation.¹¹ This concept is not simply of academic interest. The knowledge that less specialised areas can take over control in the event of injury to the functional macula is an encouragement to neurosurgeon and neurologist in the treatment of patients who have suffered cortical damage of any type.

Serum Hepatitis

PROGRESS in controlling the spread of infection with hepatitis viruses continues to be slow; for we lack a suitable animal host, culture medium, or specific laboratory test. Nevertheless the use of two more tedious methods—tests in volunteers (in the U.S.A.) and carefully controlled field observations (in Great Britain and the U.S.A.)—have thrown some light on the maintenance and transmission of serum-hepatitis virus in man. Three recent papers¹²⁻¹⁴ have confirmed earlier suspicions, which had been strengthened by brief reports by the same workers, that there exists an undefined proportion of adults—possibly as many as 0.5% at some times in some places¹⁵—who, without ever having had symptoms or signs of hepatitis, carry in their blood an agent which will produce hepatitis when injected into others. The mechanism by which the virus is maintained has long been a puzzle; for the disease is transmitted nearly always—possibly always—by injection. An obvious possibility was transmission in utero; and the observations by STOKES and his colleagues¹²⁻¹⁶ on a single mother and child, as well as several recent observations of acute and often fatal hepatitis in infants,¹⁶⁻¹⁸ strongly support this hypothesis. How long virus persists after such infection is still undecided; but it has frequently been observed that in children and adolescents serum hepatitis, though no less severe than usual when it does occur, is relatively uncommon,¹⁹⁻²⁰ whereas infective hepatitis is commonest in these age-groups. Among blood-donors carriers of virus have been shown to be

infective for several years,¹²⁻¹⁴ the longest proven period being five and a half years. All these carriers were clinically healthy, although liver damage was demonstrated in some by liver-function tests and biopsy. Of 14 donors¹³ found to be carriers, only 1 subsequently developed clinical hepatitis. Eight months after this patient recovered clinically, transfusion of his blood led to fatal hepatitis in another patient. A few previous experiments had failed to demonstrate persistent carriage after the clinical disease, but this catastrophe supports the contention that a past history of jaundice precludes donation of blood, except in an emergency. How best to prevent such accidents is still uncertain: NEEFE et al.¹³ suggest that donors should be submitted to two or three liver-function tests; but they admit that some carriers give normal results, and some patients with diseases other than hepatitis give abnormal results. In Britain such a plan has been considered several times, but deemed impracticable.

In the late war, in addition to blood for transfusion, there was a need for large quantities of a stable substance for transfusion, easy to transport and store in any part of the world. Out of this arose the method of freeze-drying plasma from pools derived from 50 to 1000 or more donations of blood. By the end of the war it had become apparent that this method seriously increased the chances of disseminating the virus. In the U.S.A. the problem was attacked by seeking physical or chemical methods of treating whole blood or plasma, to inactivate virus. The hepatitis viruses had already been proved extremely resistant to heat at the highest temperatures that would not involve change in the constituents of the serum or plasma, and to the usual preservatives such as phenol and tricresol.¹⁵ Each treated substance had to be tested on small groups of volunteers. Progress was slow, and the difficulties of reaching conclusions and relating these to large-scale production was shown by the work with ultraviolet light (U.V.L.).²¹⁻²² In Great Britain the first step was to reduce the size of plasma pools to one where the risk would be relatively slight; each pool was restricted to 8-10 donations, yielding four or five 400-ml. bottles of plasma. The wisdom of this measure was evident from a survey of its application in the period October, 1945, to March, 1948.²³ When, however, the early successful results from the use of U.V.L. treatment were reported from the U.S.A.,²¹ it was thought advisable to see whether this provided any further protection; and a preliminary account of a comparative trial of U.V.L.-treated large-pool plasma (600-800 donations), small-pool dried plasma, and whole blood is given on p. 1328 of this issue. Use of small-pool plasma has been clearly vindicated. What is even more gratifying is the drop in incidence of serum hepatitis among those who received whole blood or small-pool plasma in 1952-53, compared with the 1945-48 series²³; parts of the two series were in the same area. This incidence is also very much less than that reported in recent years from the U.S.A. after transfusion of blood or plasma. Any of several different factors may underlie this reduction, but none can be established.

A further method of dealing with plasma has been suggested by ALLEN et al.,^{24 25} in Chicago, who point out that all the present methods of storage tend to preserve any virus present, and that viruses in general tend to die more rapidly in the liquid state at room temperature (21°–30°C). They also dispute the common assumption that proteins in the plasma undergo early and serious deterioration, and they claim that plasma which has been stored for six to nine months at room-temperature is satisfactory for preventing or treating shock or hypoproteinaemia. ALLEN and his colleagues used pooled plasma from 25–32 donors, and found that 4% of their pools were contaminated (presumably with bacteria or moulds). Bacterial contamination would seem to be one of the main hazards of such material. Additional refinements of filtration and treatment with U.V.L. (neither of which was applied by ALLEN) have been suggested as useful adjuvants; but these measures seem to be just as laborious as preparing small-pool plasma. The Chicago workers claim that they have greatly reduced the risk of hepatitis from plasma by storage for six months at room temperature, and this agrees with the results from a questionnaire completed by 124 blood banks which had used the method; but the Chicago workers' own results in 1942–53 are not so convincing. From the article that we publish this week it seems that in this country such material is unlikely to carry less risk than small pools (dried) as normally prepared here. Furthermore, MURRAY²⁶ has recorded hepatitis with jaundice in 1 of 5 volunteers who received only 1 ml. of a known infected pool which had been left for six months at room temperature.

Though there is still no certainly effective method of treatment which is harmless to blood or man, one can feel relatively safe in Great Britain when administering fresh whole blood, or plasma prepared from pools of 8–10 donations. These carry about the same risk—a risk that is very small indeed.

Certification

SINCE well over half the patients admitted to our mental hospitals now enter voluntarily, the stigma of mental illness is evidently fading. This wide acceptance of voluntary treatment shows, too, that the stigma attaches not so much to treatment in a mental hospital as to legal and compulsory detention in a mental hospital—to judicial certification, in fact. This point was brought out by witnesses from the Ministry of Health and the Board of Control who recently gave evidence to the Royal Commission on the Law relating to Mental Illness and Mental Deficiency.²⁷ It is possible, though not perhaps

probable, that as enlightenment spreads, and mental illness in general is regarded with more equanimity, the stigma attaching to certification, too, will fade. But at present, at all events, the public think of the patient under certificate as “really mad,” whereas they assume that a voluntary or temporary patient is suffering merely from some mild aberration or nervous breakdown. Again, certification of a member of a family may harm the employment prospects of other members—and of course the prospects of the mentally sick man himself, when he recovers. Since recovery often takes place in a matter of months, certification must often appear to patients as an unwarranted and damning piece of aggression by society. No other sick person is penalised in quite the same way. One method of changing the public attitude to certification would be by gradual education; but a quicker way, favoured by the Ministry and the board, would be to admit all patients to hospital without a judicial certificate, and only later to certify those whose dangerous or self-punitive impulses had not been modified by treatment. At present even a voluntary patient must apply in writing to be admitted to a mental hospital, though if he needed treatment in a general hospital his family doctor would arrange it for him. His admission, moreover, is notified to the Board of Control, which makes the whole undertaking seem more formidable than it is. Whatever virtue or value there was at the outset in such notification, the witnesses were agreed that it has now evaporated, and that voluntary patients ought to be able to use their mental hospitals with as little formality as they do a general hospital.

When a patient is unable to say whether he is, or is not, willing to accept mental-hospital treatment, the law already provides that he may be admitted without certification as a temporary patient.

The application is made by the spouse or other near relative, and is supported by the recommendation of two doctors, and these documents constitute authority for the detention of the patient up to six months, provided he does not in the meanwhile recover the power to express his willingness or unwillingness to remain. If towards the end of the six months it seems probable that he will not recover before the time runs out, but that he may do so soon afterwards, the period may be extended by two further periods of three months; and if then he still needs treatment, and is unable or unwilling to agree to remain as a voluntary patient he must either be certified or discharged.

This is a tried and valuable way of postponing certification for a patient who has lost his volition; but of course such patients are few, and their situation is very different from that of the patient who objects strongly to being detained in hospital. When it is obvious to everybody except the patient himself that it would be a good thing for him to have treatment in hospital, should it be possible, Mr. ARMER asked at the hearing, to force him—without a judicial order—to have it? And he answered, for the Ministry and the board, that, on balance, they thought it ought to be possible—that indeed it is highly desirable, both for him and his relatives, that he should be able to have treatment for a temporary period (say six to twelve months) without being certified. It could be done, Mr. ARMER suggested, by arranging for the unwilling patient to be taken to hospital by the duly authorised officer, under section 20 of the Mental

27. Minutes of Evidence, first day. H.M. Stationery Office, 1954. Pp. 69. 3s.

The members of the commission are Lord PERCY OF NEWCASTLE (chairman), Mrs. H.A. ADRIAN, J.P., Mr. C. BARTLETT, R.M.N., Mrs. E. M. BRADDOCK, M.P., Sir RUSSELL BRAIN, F.R.C.P., Sir CECIL OAKES, J.P., Dr. T. P. REES, Dr. D. H. H. THOMAS, Dr. J. GREENWOOD WILSON, and Miss H. M. HEDLEY (secretary). The Ministry of Health and the Board of Control were represented by Mr. I. F. ARMER, deputy secretary of the Ministry and chairman of the board, Mr. H. R. GREEN, legal senior commissioner of the board, and Dr. W. S. MACLAY, medical senior officer of the board, and a principal medical officer of the Ministry.

Treatment Act, or a modified form of it, and kept there for three to seven days. His detention beyond this time would depend on medical recommendation, which instead of operating for fourteen days as it does with the present reception order would last for up to six months. It could perhaps then be extended for a further six months, thus delaying judicial certification for twelve months in all. Whether a person should be deprived of his liberty for twelve months merely on medical recommendation needs careful thought of course; but the Ministry and the board are convinced that on the whole it would be more to his advantage, and that of his relatives, than is immediate certification.

Such delayed certification, as Mr. WOODLEY reminds us in the correspondence columns, is already being tried in Northern Ireland, apparently with good success.

As a means of admission to a mental hospital, judicial certification has been abolished there, all patients being

admitted as either voluntary or temporary patients. The application for admission of a temporary patient must be made to the medical superintendent by a relative, or—if no relative is available—by a welfare officer, and must be supported by a recommendation from one doctor, who must give reasons why he thinks the treatment necessary. The patient is admitted on these documents, and the initial period of temporary treatment may last twelve months. It may be extended, however, on application to the Northern Ireland Ministry of Health and Local Government, for two further periods of six months, and in exceptional circumstances a further extension is possible—over two years, in all. If, however, the patient is then thought to be unlikely to recover, and further mental hospital care is needed, a judicial order must be obtained.

It seems entirely reasonable that a patient should not be certified until he has had a period of skilled treatment, and that it should only take place when he has been for some considerable time in a mental hospital under psychiatric observation. As Mrs. BRADDOCK put it, "certification for a mental complaint should be the last resort, not the first."

Annotations

H.M. OVERSEA CIVIL SERVICE

TODAY many countries are moving steadily towards self-government. They do so with the good will and help of the Colonial Office and the Colonial Service. And it is a sign of this good will that all are anxious to ensure that such skilled help should continue to be available to these young governments.

Today all those who govern have to lean heavily on the expert, and the people who are called to govern these rapidly developing countries face enormous technical problems, with very few doctors, engineers, scientists, or administrators of their own; and, as the leaders in these territories themselves recognise, their need for British experts will remain for some time to come. The undertaking lately offered by Nigerian delegates shows¹ that these new countries are aware of their responsibility towards the men and women whose help they seek. But the Secretary of State for the Colonies feels that he too shares the obligation to safeguard the legitimate interests of these officers who were appointed under his name. To meet this changing situation he has, in a white-paper, described his plans for the *Reorganisation of the Colonial Service*.²

Since 1930 the members of this service have been employed and paid by the government of the territory where they worked, but they have been under the "general direction and patronage" of the Secretary of State for the Colonies. If the territory where they are working becomes self-governing, these officers, the white-paper suggests, are entitled to expect that the terms of service offered them shall not be less favourable than their present ones; that their pensions and other benefits shall be safeguarded; that they shall be eligible for transfer and promotion to posts in other territories; and that if their employment is ended because of constitutional changes they shall be given adequate notice and alternative employment or compensation. The Government in the United Kingdom is prepared to secure them these rights by formal agreement with any country which attains self-government, and as a first step the Government is compiling a list of all the officers entitled to these rights, and giving them the new name of Her Majesty's Oversea Civil Service. Those eligible for admission to the new service will include members of the Colonial Service (including the Colonial Medical

Service). In future any offer of appointment made by, or on behalf of, the Secretary of State will include a clear statement whether it carries with it membership of the new service or whether the officer's contract is solely with the territorial government. The Government hopes that "this new form of service will ensure that qualified men and women may be attracted to come forward in future as in the past, in a spirit of confidence, enthusiasm and partnership, to help the oversea governments and peoples along the path of social, economic and political progress."

GENETIC PREDISPOSITION TO DISSEMINATED SCLEROSIS

WHEN the genetic predisposition to an illness is weak its existence can be tested in two ways. Careful twin studies may reveal greater concordance of identical twin pairs, compared with fraternal twin pairs; or large-scale family studies may show that the disease prevails in the near relations of the index cases at a rate definitely higher than in the general population.

No major twin studies have yet been made for disseminated sclerosis. Thums¹ in 1949 found 1 of 20 identical twins also affected. This indicates that genetic predisposition, if present at all, must be weak. Four family studies have each given essentially similar results, though the workers have differed in the interpretation of their findings. Curtius and Speer² were the first to publish figures suggesting that near relations are unduly liable to be affected. Subsequently Pratt³ found 6 of 609 siblings and 7 of 1441 parents affected. Müller⁴ in Sweden last year and Allison and Millar⁵ this year have reported much larger series. Müller studied the families of 750 index cases and found 5 of 1493 parents, 22 of 2815 siblings, and 4 of 692 children affected. After correction for age he calculated that these figures represented incidences of 0.3, 1.0, and 2.3. Allison and Millar studied every case they could find in Northern Ireland—700 in all (476 "probable," 145 "possible," and 79 "early")—and in 2939 siblings they found 34 affected (about 1%). They also found that the highest incidence in the general population for any area or age-group (County Fermanagh, aged 40–59) was only 0.18%.

2. Colonial no. 306. H.M. Stationery Office, 1954. Pp. 7. 4d.

Thus it is generally agreed that the proportion of siblings affected is about 1%—though the risk of a sibling developing the disease is probably rather higher than this when allowance is made for age and for the degree to which the probability of ascertainment is independent of the number of affected individuals in the family. The risk to parents and children is probably of the same order. But these figures mean little except in comparison with the risk to a random member of the general population, and this risk is less well established. Müller alone of these workers felt that the incidence he found in near relations might not differ significantly from that in the general population; but he was not aware at the time of the findings in Northern Ireland. While this general risk no doubt varies from country to country, it seems unlikely to exceed 0.2%. Therefore the risk to near relations is probably at least five times greater than that to others.

There are several possible explanations of these findings besides the obvious one that genetic factors predispose (though rather weakly) to disseminated sclerosis. One is common environment; but this is unlikely to extend over three generations. A more probable explanation is that the familial cases may have been, not disseminated sclerosis, but some form of genetically determined spinocerebellar ataxia. The workers concerned were all aware of this possibility (Allison and Millar show that the figures for the "probable" cases do not differ from those for the whole group), and they agree that differential diagnosis may be difficult.

ACCIDENT-PRONENESS IN MINERS

A NOT wholly unattractive picture of the accident-prone was drawn for us in 1943 by Flanders Dunbar.¹ She found them unusually healthy, seldom off work, lively-minded, happy-go-lucky, agin the government, and inarticulate about their feelings. Since she wrote about them, however, some doubt has been thrown on their existence. They are, in any case, difficult for statisticians to lay hands on, for after an accident anyone—accident-prone or not, and whether from choice or necessity—may change his job. However, as we have noted,² some clinicians are inclined to think that temperamental qualities do affect liability to error, and so to accident. Mr. J. W. Whitfield³ in an investigation which should mollify the most exacting of statisticians, has studied disabling accidents in one colliery between July 1, 1944, and Dec. 31, 1946, and has drawn some conclusions based on an actuarial risk, calculated for each man according to the number of shifts worked, the place of work, and the type of work done. Discrepancies between calculated risk and actual accident experience were analysed, and accident-proneness demonstrated: that is, there were measurable individual differences in accident susceptibility.

Men who had worked in the mine for only a short time were excluded from the study. That left 1384 miners who, during the period covered, suffered 1265 accidents severe enough to keep most of them from earning full wages at their normal work for more than three days. Some accidents, presumably, are unavoidable: if a thunderbolt strikes one, or the earth abruptly swallows one up, no amount of resource and sagacity, no expertness in motor response, is likely to preserve one from damage. Such catastrophes apart, however, accidents can be considered, in Whitfield's phrase, as "failure to make an adequate response to a hazardous situation." We may fail either because we do not appreciate the hazard in time and decide what response to make, or because we do not make the appropriate response quickly enough. Such failures in appreciation

and in performance can be demonstrated by appropriate tests, and the accident-prone men in Whitfield's study gave poor scores in one or other of the two groups of tests. The type of accident-proneness differed with age. The younger accident-prone miners were heavier and of better physique than their contemporaries, and their motor control and coördination were good; but they scored very poorly on tests of perceptual, memory, and cognitive processes. The older accident-prone men, on the other hand, scored average or above average in the perceptual and cognitive tests, but were much poorer in motor control and coördination. Perhaps the younger accident-prone leave this industry before they reach middle age: or perhaps they learn to keep out of trouble.

In the older men, accident-proneness may have been slowly developing as motor ability declined; and perhaps perceptual and cognitive ability were declining too. A man who is deficient in motor ability commonly compensates for this by anticipation, but as age advances he may become less able to do this. Whitfield suggests that if further studies confirm his findings, the "older type" of accident-proneness might be watched for and detected early. Methods could then be devised to protect those in whom it was developing. Accidents are undesirable, in the interests not only of the men but of the industry: the older men are of great value, and the loss of their skill, even temporarily, is serious. The younger accident-prone present a different, and more difficult, problem. Whitfield found some evidence that their temperamental development might have been unfavourably affected by adverse factors in childhood and upbringing, but, as he rightly says, "this is not susceptible to direct action by the industry." The proper way of tackling them, he concludes, is by training: for though it may be impossible to teach caution to those who are temperamentally careless and happy-go-lucky, yet they can be taught to use specific working methods appropriate to their lack of foresight. It will be something, he thinks, if safety officers recognise that good motor coördination alone is not enough.

HEEL LESIONS IN RHEUMATOID ARTHRITIS

It is well known that in rheumatoid arthritis the distribution of the joint lesions spreads centripetally as the disease progresses, but in the early stages only the hands and feet may be affected. For early diagnosis, therefore, attention is particularly directed to the hands, which show characteristic changes; in the feet early lesions are perhaps less easily recognised, and the changes produced in the tarsus by rheumatoid disease less well known.

Bywaters¹ has described heel pain as an early or even a presenting symptom in rheumatoid arthritis, and has reported a small series of cases in which he investigated the underlying lesions. He found two different heel lesions, occurring with about equal frequency, and usually together, in 2-3% of unselected cases. The first, a sub-Achilles bursitis, involves the bursa which lies between the tendon near its insertion and the fibrocartilage of the posterior surface of the calcaneum. It is manifested clinically by swelling, pain on walking, and tenderness, and radiographically by rarefaction and erosion of the subjacent bone. The second lesion consists solely in erosion of the plantar surface of the calcaneum, involving the plantar spur and the area behind it. In both lesions the histological appearances of rheumatoid granulation-tissue are found, including the cell formations typical of the rheumatoid nodule. Healed lesions examined at necropsy showed obliteration of the sub-Achilles space and loss of normal fibrocartilage from the bone surface at the site of erosion.

2. *Lancet*, 1953, 1, 730.

3. *Brit. J. Industr. Med.* 1954, 11, 126.

1. Bywaters, E. G. L. *Ann. rheum. Dis.* 1954, 13, 42.

The type of heel pain to which these lesions give rise includes the "achillodynia" described many years ago, and hitherto regarded as a complication of chronic infection—usually gonorrhoeal. Bywaters believes that rheumatoid arthritis may be the commonest cause of these lesions, and that this diagnosis should be especially kept in mind when heel pain is among the presenting symptoms.

RECEPTION HOME

"There are several doctrines about reception homes: the approach psychometric; the approach analytical; and the approach nihilistic, the last displayed by those who claim to have opened such homes and closed them again. Perhaps more precious than any is our own pose of being plain honest-to-goodness social workers. That child, we say, is best served by the reception home who never goes into it."

In *Case Conference*, a new journal for social workers and administrators, Mr. Kenneth Brill,¹ from whom we quote above, describes the achievements of a reception centre during its first year of life, and with pleasant irony tells something of the strength and weakness of social work in this setting. The aim of the staff is to get the children who come into the centre either safely back to their mothers or else into a settled home life with someone who will take the mother's place; and their results speak for themselves: of 47 children under the age of fifteen who came into the centre during the year ending March, 1953, 35 have since been restored to their families, 6 are in foster-homes, and 6 are still in group care.

The children come into the centre for the usual reasons—on a "place of safety" order, because of temporary difficulty at home (such as admission of the mother to a mental hospital or sanatorium), because the family has been evicted, or because they have been committed to care by a court, for delinquent behaviour. The first thing they notice is that they have not come to a permanent haven: they see other children coming and going, and they probably derive a feeling of safety from the fact that they are all in the same boat—temporarily away from a home to which they hope to return. This helps them to accept the situation and look forward to a coherent plan for the future; and they are quite aware of what is going on, it seems.

A boy of ten, committed by the juvenile court for larceny, and rejected by his mother, got tired of waiting in the home, and accosted the boarding-out officer with the inquiry, "When are you going to make a plan for me?"

A child who has led a roving life with an evicted parent is sometimes at a loss to see why he should change his arrangements. They have, as far as he can see, worked fairly well, and they have, at all events, generally supplied him with an independent spirit. An eleven-year-old, sounded on the question of a foster-home, replied maturely: "I don't want to live with any stinking auntie, whatever the Government wants."

The results achieved by this reception centre form part of the experience of the Devon Children's Committee, which set it up. The county as a whole can claim that of 233 children under fifteen who came into care in the year ending March, 1953, only 20 remained in institutions a year later. Children for whom the committee foresee the end of their stay in care (classed as short-stay children) are now nearly all sent into foster-homes from the start; and, in particular, admission of short-stay children to a residential nursery has almost ceased. There were 132 short-stay children among the 233, and all are now back in their own homes. Moreover, nearly half the long-stay children, whether committed

by the courts or not, went home within two years, and two-thirds of the remainder are now in foster-homes.

This first year's experience, Mr. Brill says, contains an administrative lesson. Nowadays children's committees are urged to invest in plenty of qualified child-care officers; and those who do so will be surprised at the dividend. The chief gain—which is both spiritual and financial—is that only a tiny fraction of the children received ever need to be in residential care: residential nurseries and family homes can be closed down. "Invest," he says, "in bricks or mortar or in properly trained social workers, but not in both at once."

The reception home has proved to be a terminus for several lines of social work; and, since some twelve statutory agencies² have an interest in protecting children from neglect and ill-treatment (quite apart from the children's officer, her field worker, the staff of the reception home, almoners, police, probation officers, private people such as doctors and clergy, and all the voluntary agencies), Mr. Brill advises those who are opening such homes to have a room large enough to take twenty or more social workers at a time at a case-conference. Fortunately few families attract the interest of more than six or eight agencies; but representatives of all these must be present at the case-conference, or else—as he illustrates from an authentic case—the one forgotten agency will take independent action astonishing to the rest. The difficulty, he says, is in forecasting which agencies to invite. Nevertheless the justification of such gatherings lies in the experience of children now back with their families or beginning a new life in foster-homes.

SURVIVAL OF DRIED CULTURES

BACTERIA survive for long periods in the dried state, and drying under controlled conditions is now a standard method for maintaining stock cultures for teaching or reference purposes. The techniques used may be simple or complex, but all involve the destruction of 90–99% of the organisms being dried. In September, 1953, the British Commonwealth Collections of Micro-organisms organised a discussion of drying methods to which workers from different parts of the Commonwealth were asked to contribute their experiences. Papers circulated before the meeting are included in the report of the discussion,³ which ranged from the problems of the designer of apparatus to the technical methods for checking the viability of the dried cultures.

The discussion showed that the fundamental principles underlying the method are still only imperfectly understood and that many of the procedures are empirical. The most important single factor affecting viability of the dried product seems to be the material in which the micro-organisms are suspended, and of glucose, the addition of which was first suggested by Fry and Greaves,⁴ is the most successful of the additives. Record and Taylor⁵ have recently shown that bacteria themselves, presumably by autolysis, can contribute some protective factor, so the survival-rates of heavy suspensions are greater than those of lighter suspensions, but the difference is not as great as the glucose effect. Ultimately it may be possible to correlate survival-rates with residual moisture content, but technical difficulties of determining residual moisture have so far prevented this. Apparatus described at the discussion may bring moisture determination within the range of routine procedures.

WITHIN recent times the number of actions against hospitals has increased. For this increase there appear to be four main reasons: (a) the payment of doctors from public funds, (b) the national ownership of hospitals, (c) the effects of the Legal Aid and Advice Act, 1949, and (d) certain changes in the outlook of the doctors themselves.

In the days when the consultant staffs of voluntary hospitals were unpaid, the fact that their service was gratuitous made them as immune against charges of negligence, in fact though not in law, as the barrister is today. The practice of bringing actions against hospitals may be said to date from the beginning of public ownership of hospitals, when certain of the poor-law hospitals and institutions "appropriated" by the local authorities in 1930 took on the functions of general hospitals; and it advanced further when the ownership of hospitals was taken over by the State in 1948, since when neither the public nor their legal advisers have hesitated to bring actions against members of the medical staffs—knowing that behind them are virtually unlimited resources. (Also the fact is not unknown to the public that all prudent doctors are insured against actions through one of the medical defence societies.) Under the Legal Aid and Advice Act, 1949, any man with a reasonable cause for action can be given the means of seeking a remedy, and State funds are now available even for action against the State. And finally the medical profession no longer appears united, presenting an impenetrable front. Some doctors do not hesitate to take sides in the lay press, and the medical press is a happy hunting-ground for the journalist. The serious effects of conflicting evidence by expert witnesses will be referred to later.

NEGLIGENCE IN LAW

Negligence may be of two kinds, criminal and civil. Criminal is distinguished from civil negligence in that in the former the degree of negligence must be a criminal one; it must be a *wicked* negligence, or negligence which shows so little thought for the safety and life of others that it merits punishment, while in the latter damages are sought from the wrongdoer to recompense the sufferer. Whereas the degree of negligence which will support a claim for civil negligence may not be sufficient to constitute criminal negligence, the degree sufficient to amount to criminal negligence will be more than enough to support the civil kind. A charge of criminal negligence does not preclude the instituting of civil proceedings on the same facts.

In common law civil negligence is a tort, defined as a civil injury or wrong, the remedy for which is unliquidated damages—i.e., damages which are not ascertained previously but are left to the court to determine in its discretion. (There are of course other remedies for a tort, such as an injunction; but they are in addition to the damages, and do not apply to negligence.) It has been said that a tort is "a civil wrong for which the

remedy is a common law action for unliquidated damages, and which is not exclusively the breach of a contract or the breach of a trust or other merely equitable obligation,"¹ but the same facts might give rise to a tort and also to a breach of contract, for the doctor-patient relationship is usually one of contract. Nevertheless when there is a breakdown in this relationship owing to some malfeasance on the part of the doctor it is generally under the heading of tort that a claim is made.

Negligence, as a tort, is the breach of a legal duty to take care which results in damage, undesired by the defendant, to the plaintiff.² It consists, therefore, of three elements, and it is only if these three exist together that an action for negligence can arise. They are (a) a legal duty to take care, (b) a breach of that duty, and (c) damage arising from the breach.

(a) No problem arises with regard to the duty of care, because it is obvious that the doctor-patient relationship involves this duty.

(b) Speaking generally, a breach of duty is the omission to do something, or the doing of something which should not be done by a reasonable man, and in this context a reasonable man is generally taken to mean the ordinary man in the street. However, where members of a profession hold themselves out as exercising particular skill, this must be of the order which can reasonably be expected from members of such profession, having regard to the knowledge of the time. A doctor will be as liable if he renders treatment voluntarily to an unknown person in a street accident which he encounters merely when passing, and is negligent, as he would be if treating one of his regular patients, except that the circumstances in which he is compelled to work will, of course, be taken into account. Whether or not there has been a breach of the duty of care is a question of fact for the jury to decide, or for the judge should he be sitting without a jury.

There are no degrees of quality in civil negligence, and although such terms as "slight," "moderate," and "gross" may be used they have no bearing on whether or not negligence exists.

(c) The result of the breach must be damage to the sufferer. If there is no damage there can be no negligence. The object of an action for negligence, therefore, is to obtain damages for the plaintiff for a wrong suffered—not to punish the defendant. There are, however, other possible results of such an action and they will be discussed later.

In passing it should be mentioned that an action for negligence is one of the remedies for breach of a statutory duty. The damage suffered must be that which it was the purpose of the statute to avoid and not other damage resulting from the breach. It will be interesting to see whether there are any developments along this line in future, relative to the statutes, said to number about 180, which now have some bearing on the practice of medicine.

THE CONDUCT OF A CASE

The case may never reach the courts. The negligence may be admitted, the amount of damages may be agreed between the parties, and after settlement the matter may end without publicity, the whole business being conducted privately between the parties and their representatives. Even when a writ has been issued against the defendant, the matter may be settled by the parties before the action comes up for trial.

On the other hand, though the defendant may admit negligence, and may be willing to pay what he thinks is a reasonable amount as damages, the injured party may regard the amount as insufficient. The case is then taken to the court for an assessment of damages, and perhaps (if more than one person has suffered) for an apportionment.

1. Salmon, *Law of Torts*, 1953, p. 15.
2. Winfield, *Law of Tort*, 1950, p. 405.

If negligence is denied, the object of the action is to decide whether there was negligence. If the case is proved, damages will be assessed. The burden of proving negligence rests on the plaintiff, and he must prove not only that the defendant was negligent but also that this negligence caused the injury.

There are, however, cases where, though the plaintiff can prove that an accident has happened, he cannot prove how it happened, and consequently cannot show that it was due to the negligent act of the defendant. There are many acts which, performed in the normal way, lead to no untoward happening; and in which, should anything go wrong, it might be presumed that it was due to the fault of the person in charge of or performing the act. This has given rise to the rule of *res ipsa loquitur*. If the accident speaks for itself, the plaintiff does all that is required of him if he proves the event, and it then becomes the duty of the defendant to show that it was not due to negligence on his part. If, however, the defendant can show that the accident could have occurred either by his negligence or without negligence the burden of proof moves once more to the plaintiff to show that it was due to negligence.

A case is proved or disproved in the courts by means of evidence, which was defined nearly two hundred years ago as "that which demonstrates, makes clear or ascertains the truth of the very fact or point in issue, either on the one side or on the other."³ There are three types of evidence:

- (i) Oral evidence—i.e., the testimony of witnesses.
- (ii) Documentary evidence—i.e., the production of documents.
- (iii) Real evidence—i.e., the inspection of things.

(i) *Witnesses* may be of two kinds. Firstly, there is the ordinary witness of fact who makes a statement of fact and gives no opinion on it. Thus a man in the street may say that he saw a man fall from a roof, and when he picked him up he found that he was unconscious and had a large cut over the top of his head. Secondly, there is the expert witness who may give evidence of fact and follow this up with an opinion. If, for example, the man who fell from the roof was taken to a hospital, the medical officer may say that he saw the man on admission, that he was unconscious, and that he had a large cut over the head. Treatment was given and the patient put to bed in a ward where he died in half an hour. These are facts; but the doctor may say in addition that in his opinion death was due to compression of the brain due to hæmorrhage, following injury to the head. He then becomes an expert witness. Alternatively the expert witness need not give evidence of facts before giving his opinion on them, but may give his opinion on facts which have been established by others. He may, for example, apply his special knowledge and experience to the facts already known to the court. Normally it is for the court to form opinions from facts given by witnesses but when the court cannot form an opinion because the subject is technical, or because special study or skill is required, then experts may be called.

(ii) The production of *documents* means the production before the court of any written or inscribed matter relative to the case. The term is used in its widest sense to mean anything permanently recorded, and includes hospital and doctors' notes of cases. Privilege, in the sense that they contain information of a confidential nature which was obtained in a professional capacity from patients, is not attached to these notes, the production of which can be ordered by the court. If, however, their production would tend to criminate the person producing them, then privilege may be claimed.

(iii) The term "*things*" means anything other than documents as defined above. Thus there may be produced in court the splint used in a particular case, or an anæsthetic machine may be brought as an exhibit to explain how it works. In the case of documents and things, witnesses usually come forward and testify about them either as to fact or in an expert way.

A plaintiff or defendant is under no obligation to engage a lawyer to advise him and to look after his interests, or to represent him in court; but in almost all cases litigants are represented, and today there is no reason why any person with a reasonable case—this term is used to eliminate frivolous and vexatious actions—should not have legal assistance, however poor he may be.

Where he is engaged, counsel's duty is to further the interests of his client by bringing before the notice of the court all the facts which, with fairness, will support his client's case. Counsel does this by presenting the evidence in favour of his client in what is known as examination-in-chief. After each witness has been so examined, opposing counsel does his best to upset or belittle this evidence by cross-examination. Cross-examination is never pleasant, and medical men, as do others, sometimes feel that they are being personally attacked and resent this. It should be mentioned here that barristers do not enjoy pulling to pieces a member of another learned profession; it is simply their duty to do so to further their client's interests.

After cross-examination the first counsel may re-examine his witness to obtain enlightenment on any question which has been brought out in cross-examination and which is not clear. It is hardly necessary to add that the evidence of a medical man is not privileged in respect of knowledge which he has acquired in a professional capacity, and that the court can compel the doctor to answer questions. Failure to do so will result in his being punished for contempt of court.

THE EFFECTS OF PUBLICITY

The disquiet in the medical profession at the recent trend in litigation is not entirely due to the increase in the number of cases which are being brought against the hospitals and doctors. It arises partly from the way in which cases are sometimes reported in the lay press. Thus the plaintiff's case on the first day may be reported in full, whereas on succeeding days the defence, and final decision, may be reduced to one paragraph. We make no suggestion of deliberate unfairness: it is merely that, after a day or so, other news makes headlines.

Press reports may have an impact on three sections of the community—the general public, the defendant doctor, and the medical profession generally. No small part of their effects is due to the conflict of opinion of expert witnesses engaged to support the plaintiff and the defendant; for those employed by each side are called because they will support the evidence which one or other side can bring forward. Suppose, for example, that each side has three expert witnesses. This means that on each side there are three medical men who may give diametrically opposite opinions to the other three and, this being so, the layman must assume that one side is right and the other wrong. It appears to him also that, given one set of circumstances, three doctors would have done one thing and three others the opposite. What is not apparent to the layman is that the defendant doctor may have been in the position of having to make one of these very decisions. Using all possible care and skill he selects one which may be right or wrong: it is a selection which is later supported by one set of witnesses, and the fact that it has proved unfortunate does not imply negligence. An expert witness may say that he would have done something different; but it is sometimes difficult to see how he can put himself—post mortem so to speak—in the position of the defendant doctor, who may well have less experience and knowledge than the witness but may nevertheless have shown all the care and skill within his competence.

These divergences of opinion between expert witnesses, each of whom may claim that his opinion on the given facts is the correct one, may have an unexpected effect

3. Blackstone. Comm. III. 367.

on the case; for in order to reach a decision the judge and jury are thrown back on their own common sense. It is possible that some of the very heavy damages awarded recently would not have been given if the true prognosis had been more clearly understood. Moreover, reports of such actions can have a damaging effect on public confidence, for a patient in the future may suffer extra fear and trepidation when he is ill, or undergoing special manipulations.

It has been noted already that the object of an action for negligence is not the punishment of the defendant doctor. But in fact he may be severely punished, in that he suffers mentally, sometimes physically, and possibly financially. By reason of the trial his professional confidence may be shaken or lost; the mental worry may lead to a physical breakdown, and he may suffer a loss of practice income.

The effect on the medical profession generally may be cumulative, for it may lead to a state of affairs where the doctor's first interest will be to make sure that he is fully protected against any possible charges. We may not come to the point of the surgeon taking his legal adviser into the operating-theatre with him, but the patient might conceivably be asked to sign an indemnity form against all liability before treatment is commenced.

DISCUSSION

The practice of medicine being one which demands that the mind of the practitioner should be free from fear and untrammelled by extraneous worry and care, it might be possible to postulate a set of principles, and see whether there are any means by which these could be fulfilled without prejudicing the rights of any other person should the practitioner fail in his duties. What the doctor requires are freedom of action to use methods of diagnosis and treatment which are in his judgment best for the particular case being dealt with; freedom from fear of consequences of a genuine mistake or of an untoward and unforeseen reaction on the part of the patient, and freedom from fear of frivolous actions and vexatious litigation.

How can this freedom be ensured? In regard to negligence, doctors are not members of a privileged profession. They must bear the responsibilities for their actions as do other members of the community, and this is not altered by the fact that they must show care and skill. What is causing concern today is not that doctors are liable for negligence—for no-one will deny that if a wrong exists it must be righted—but the way in which the existence or absence of negligence is decided.

A number of alternative means could be found for deciding claims for negligence. Thus the position might remain as at present, cases of negligence against hospitals and doctors being tried openly in the courts by a judge sitting with or without a jury. Or the case might be tried behind closed doors—though such a suggestion strikes at the roots of English justice and would be open to the objection that it creates a special procedure for medical negligence, as compared with negligence in general. Alternatively a degree of privacy which would appeal to the medical profession might be achieved if the publication of medical evidence in the lay press could be limited like the publication of details in divorce and certain other cases. The doctor giving evidence would then feel that the professional confidences which he had obtained were not being so widely broadcast, and the medical histories in the hospital notes would once more assume a confidential nature. Furthermore the confusing and contradictory opinions of expert witnesses would no longer harass the public and tend to destroy confidence in the medical profession.

From the legal point of view it would be impracticable to do away with the expert witness; for he is necessary for the preparation of the case, and his examination and

cross-examination are essential for its efficient conduct in court. The expert witnesses might, however, be limited in number to one on each side, and one or more medical assessors might sit with the judge. These assessors, who would have to be doctors of undoubted ability and integrity, would assist the judge on points in the evidence which were not clear. They might also be given power to examine the plaintiff, and would thus have first-hand information which would assist in assessing the amount of damages to be awarded. The assessors might be drawn from a panel based on the assize circuits. Nautical assessors already assist in Admiralty cases, and thus form a precedent for the institution of such a panel in medical cases.

Another means of dealing with cases of negligence would be to entrust them to tribunals specially constituted for the purpose. The National Health Service Act, 1946, could be amended by an Act declaring that all actions for negligence in which damages will have to be met from public funds shall be heard by a tribunal and not in the ordinary courts. Such a tribunal could act in one of several different ways. It might act like the old "grand juries" (abolished some years ago), deciding merely whether the prima-facie evidence of negligence was such that the case should be referred to the courts for trial. Or it might act as a court of law, hearing all evidence, deciding whether there was negligence, and assessing damages where appropriate. Such a tribunal might meet in private or be open to the public. If the latter it would differ in no essential respects from the courts.

Finally, it would not be impossible for the issue of negligence to be taken out of the case entirely and to make the liability strict. Patients attend hospital for help and treatment. They expect to obtain benefit from this, and if they do not obtain it they may feel aggrieved and think that they should receive recompense for this failure. The tribunal could be given power to award compensation—either as a lump sum or on a fixed scale—regardless of the cause of the failure and who was responsible.

CONCLUSIONS

When preparing this paper we consulted a number of people, including lawyers, both practising and academic. In our opinion drastic changes in the law are not indicated, and we believe that the use of medical assessors by the courts, the limitation of the numbers of expert witnesses, and a reasonable degree of restraint in the publication of medical evidence, would go far to improve the present position.

The laws of England are the results of the wisdom of centuries of judicial decisions, and in respect to negligence they are on a sound footing. What seems necessary today is not so much that the law of negligence should be changed, to suit the medical profession and the hospitals, as that medical students should be taught, and members of the medical profession have a sound understanding of, the law relating to negligence, and how negligence can be avoided.

One of the foremost ways by which a complaint of negligence may be avoided is to take the patient fully into confidence. A patient may enter hospital, and pass from one member of the staff to another, but still have little or no idea what the examinations and procedures are leading to. Nor is he always made to appreciate that some of the procedures are not devoid of risk, that the result may not be as anticipated, or that some unforeseen event may occur. If the significance of all that is taking place is explained to him and his consent obtained the risk of an action for negligence is greatly diminished. It may of course be argued that the explanation is not in the patient's interests—that if he is given too many details he will have cause to worry

and his condition will thus be made worse. But if the explanation is given in a reasonable way there can be no grounds for complaint; for "reasonable" is a word which is used frequently in connection with actions for negligence.

"Every person who enters a learned profession undertakes to bring to the exercise of it a reasonable degree of skill. He does not undertake, if he is an attorney, that at all events you shall gain your case; nor does a surgeon undertake that he will perform a cure; nor does he undertake to use the highest degree of skill. There may be persons who have higher education and greater advantage than he has; but he undertakes to bring a fair, reasonable and competent degree of skill."⁴ This dictum must apply to all; there can be no exception in the case of members of the medical profession, who should bear in mind, in respect of negligence, *Punch's* advice to those about to marry.

USE OF ANTIMALARIAL DRUGS

Recommendations by Malaria Subcommittee of Colonial Medical Research Committee

In 1949 the Colonial Medical Research Committee drew up recommendations on the use of 'Paludrine' (proguanil) in suppression and treatment of malaria; these were tentative on the basis of knowledge available at the time and were stated to be subject to revision in the light of future experience and experiment. The additional experience since gained makes it advisable to revise the recommendations and also to indicate the suitable methods of use of the different antimalarials now available. The revision is specially necessary in view of the further evidence which has been obtained that (a) some drugs which are effective in suppression of malaria are unsuitable for use in the treatment of the overt attack owing to their slow schizontocidal action, and that (b) the unsuitable use of certain antimalarials for suppression or for treatment of the overt attack may result in the development of drug-resistant strains of the malaria parasites.

Actions and Uses of Antimalarial Drugs

No single drug at present available is effective against all phases of the cycle of development of the malaria parasite; the preparation to be used for a particular purpose will be that active against the appropriate phase. The purposes for which antimalarial drugs are used are:

1. For causal prophylaxis or suppression (destruction of the parasite in the pre-erythrocytic phase or in the asexual erythrocytic phase).
2. For treatment of the overt malarial attack (destruction of the asexual parasites in the blood-stream).
3. For radical cure of vivax and quartan malaria (destruction of the late exo-erythrocytic forms).
4. For prevention of transmission (destruction of the gametocytes in the peripheral circulation or interruption of sporogony in the mosquito).

CAUSAL PROPHYLAXIS OR SUPPRESSION

The onset of a clinical attack of malaria can be prevented either by a drug acting on the pre-erythrocytic forms of the parasite (causal prophylaxis) or by one acting on the asexual erythrocytic forms (suppression).

(1) *Causal prophylaxis*.—The 8-aminoquinolines (pamaquin, primaquine) show such action, but the margin between the prophylactic and the toxic dose is too narrow to permit of their use for this purpose. The only drugs which can achieve this effect with safety are the biguanides (proguanil) and the diaminopyrimidines (pyrimethamine): their action in this respect is definite

as far as falciparum infection is concerned. Since however they act also on the asexual erythrocytic forms of all species of human plasmodia their use as protective drugs is by no means confined to falciparum infections.

(2) *Suppression*.—Drugs used for suppression show the following characteristics, advantages, and limitations.

Quinine, formerly widely used for this purpose, has several disadvantages. For the effective suppression of falciparum malaria, it may have to be taken in doses as high as gr. 10 daily, and in New Guinea even this dosage has proved insufficient. Apart from the unpleasant side-effects which may arise from prolonged administration of this amount of quinine, its association with the precipitation of blackwater fever makes it unsuitable for use as a suppressant in areas where falciparum infections are prevalent.

Mepacrine is a very effective suppressant of all forms of malaria, but has certain disadvantages which detract from its usefulness. When taken over long periods it sometimes produces skin lesions, the most common of these being a lichenoid dermatitis. Yellow discoloration of the skin, a usual feature, is a further disadvantage.

Chloroquine and *amodiaquine* are probably even more powerful suppressants than mepacrine. Their action resembles that of the last-named drug, but they are on the whole less toxic and they do not tint the skin.

Proguanil and *pyrimethamine*, as well as being causal prophylactics in falciparum infections, are effective suppressants of all forms of malaria. They also have the advantage of preventing the completion of sporogony and of being considerably less costly than the 4-aminoquinolines. There is, however, a possibility that drug resistance may appear in areas where either of these compounds is in common use, particularly if they are employed indiscriminately as therapeutic agents, though proven examples of this are very rare. Cross-resistance has been shown to exist between proguanil and pyrimethamine, so that if resistance to either of them becomes apparent a switch-over to chloroquine, amodiaquine, or mepacrine is indicated; or, if none of these is available, to quinine.

TREATMENT OF THE OVERT ATTACK¹

(1) *In non-immune subjects*.—For this class of patient it is necessary to employ one of the more powerful schizontocidal drugs, such as chloroquine, amodiaquine, mepacrine, or quinine.

Quinine has the disadvantage of its association with the precipitation of blackwater fever, and is comparatively ineffective against certain strains of malaria parasites. It cannot be relied upon to effect radical cure of infections with some strains of *P. falciparum*.

Mepacrine has a rapid action in all forms of malaria, but minor toxic manifestations and occasional psychoses of a more serious nature are definite drawbacks. The yellow tinting of the skin sometimes produced is also undesirable.

Chloroquine and *amodiaquine* are probably the most effective agents for terminating the clinical attack, and toxic manifestations of a serious nature are rare with either drug.

Neither proguanil nor pyrimethamine are sufficiently rapid in action to warrant their use in the treatment of malaria in non-immune subjects.

(2) *In subjects partially immune*.²—For the dispensary treatment of partially immune populations of malarious countries, a single-dose treatment with chloroquine, proguanil, amodiaquine, or mepacrine has proved effective. Good results have also been reported with pyrimethamine given as a single dose. In view of the possibility of drug resistance arising with both proguanil and pyrimethamine it seems wiser to reserve these drugs exclusively for prophylaxis and suppression and to use for therapeutic purposes chloroquine, amodiaquine, mepacrine, or quinine. If quinine is used, 2-5 days' treatment is usually necessary.

(3) *For emergency treatment*.—In the treatment of pernicious forms of malaria, whether cerebral, algid, or gastro-intestinal, oral administration of drugs is seldom

1. As a general principle in areas where drug prophylaxis or suppression is in operation, a different drug should be used for treatment of the clinical attack.
2. i.e., The indigenous inhabitants of malarious regions.

4. Per Tindall, C. J. In Lanphier and wife v Phipps (1838) 8 Car & Payne 474.

practicable; and since prompt action is necessary to save the patient's life, antimalarial drugs must be given parenterally in such cases. Quinine dihydrochloride intravenously has been a standard and successful treatment for many years. Mepacrine methane sulphonate may be given intramuscularly as an alternative. Recent work indicates that chloroquine is equally successful when given intramuscularly or intravenously. The intramuscular injection of quinine, still widely practised in many countries, has the disadvantage that it causes necrosis and may produce abscess. Whatever is used, as soon as the patient is able to take drugs by the mouth, all further medication should be by this route.

RADICAL CURE

(1) *Vivax and quartan malaria*.—The only drugs which are effective against the late exo-erythrocytic forms of the parasite are the 8-aminoquinolines. Pamaquin has been used for this purpose for many years, but recently primaquine has been shown by American workers to be more effective and less toxic. If an overt attack is in progress standard treatment with a schizontocidal drug should precede or accompany the course of pamaquin or primaquine.³ This combined treatment is also applicable when falciparum malaria occurs in association with vivax or malarie infections. Treatment of chronic relapsing malarie (quartan) infections is the same as for vivax cases.

(2) *Ovale malaria*.—Many infections with *P. ovale* end in spontaneous recovery. Treatment with 8-aminoquinolines is not usually necessary.

(3) *Falciparum malaria*.—There is convincing evidence against the existence of late exo-erythrocytic forms of *P. falciparum*. Any relapses that may occur are due to the persistence of erythrocytic forms. Any of the more powerful schizontocides mentioned above will usually effect radical cure.

PREVENTION OF TRANSMISSION

The 8-aminoquinolines are the only drugs which are able to destroy the sexual forms of *P. falciparum* in the peripheral blood. Proguanil and pyrimethamine have no demonstrable action on the gametocytes in the blood, but both have the property of preventing them from undergoing full development in the mosquito, so that mosquitoes feeding on patients taking either of these drugs are unable to transmit the disease to others.

Suggested Dosage

Unless otherwise stated the dosage suggested is for adults. That for children should be calculated according to age and weight.

CAUSAL PROPHYLAXIS AND SUPPRESSION

(i) *Proguanil monohydrochloride*.⁴—Adults, 100 mg. daily. Children, 0–5 years, 25 mg. daily; 6–12 years, 50 mg. daily. Adults partially immune, 300 mg. once weekly. Or

(ii) *Pyrimethamine*.—Adults, 25 mg. weekly. Children, 0–5 years, 6–25 mg. weekly; 6–12 years, 12–5 mg. weekly. Or

(iii) *Chloroquine diphosphate or sulphate*.—Adults, 300 mg. base weekly. Or

(iv) *Amodiaquine dihydrochloride dihydrate*.—Adults, 400 mg. base weekly. Or

(v) *Mepacrine hydrochloride*.—Adults, 100 mg. daily. Adults partially immune, 300 mg. once weekly. Or

(vi) *Quinine sulphate or dihydrochloride*.—Adults, 650 mg. (gr. 10) daily. Recommended only when none of the drugs listed above is available.

No suppressive regimen will be effective unless followed with the utmost regularity.

3. Mepacrine should not be given concurrently with any of the 8-aminoquinoline drugs.

4. In parts of Africa the scale of dosage for proguanil given above has been found insufficient; in Nigeria, for example, the following scale has been recommended: Adults, 100–200 mg. daily. Children, 0–1 year, 50 mg. three to six times weekly; 1–3 years, 50 mg. daily; over 3 years, 100 mg. daily.

In the case of persons who have been resident in an endemic area for some time, or who have otherwise been exposed to malaria infection, a full therapeutic course should be taken before entering on a suppressive regimen, if there are grounds for suspecting active or latent falciparum malaria.

If mepacrine is the drug employed, administration should be commenced 14 days before entering an endemic area. Administration of the other drugs should be commenced immediately before entry.

If the drug used is not affording protection in the dosage recommended, when taken regularly, a change should be made to another suppressive.

The prophylactic regimen should be continued for one month after leaving an endemic area.

TREATMENT OF THE OVERT ATTACK

(1) *For non-immune subjects*:

(i) *Chloroquine diphosphate or sulphate* 600 mg. base, followed in 6 hours by 300 mg. base, then 300 mg. base daily for 2 days. Or

(ii) *Amodiaquine dihydrochloride dihydrate* 600 mg. base, followed by 400 mg. base daily for 2 days. Or

(iii) *Mepacrine hydrochloride* 300 mg. t.d.s. on first day, 300 mg. b.d. on second day, then 100 mg. t.d.s. for 5 days. Or

(iv) *Quinine sulphate or dihydrochloride* 650 mg. (gr. 10) t.d.s. for 7–10 days.

(2) *For subjects partially immune*:

(i) *Chloroquine diphosphate or sulphate* 600 mg. base in single dose. Or

(ii) *Amodiaquine dihydrochloride dihydrate* 600 mg. base in single dose. Or

(iii) *Mepacrine hydrochloride* 300–500 mg. in single dose. Or

(iv) *Quinine sulphate or dihydrochloride* 1000–1500 mg. (gr. 15–20) daily for 2–5 days.

(3) *Emergency treatment*:

(i) *Quinine dihydrochloride* 650 mg. (gr. 10) in sterile normal saline injected intravenously and repeated in 6 hours if necessary. Not more than three injections should be given within 24 hours. Distilled water can be used as a solvent if the volume does not exceed 10–15 ml. It is imperative that quinine be injected slowly, at a rate not exceeding gr. 1 per minute. Or

(ii) *Mepacrine methane sulphonate* 375 mg. or *mepacrine hydrochloride* 300 mg. intramuscularly, repeated in 6 hours if necessary. Or

(iii) *Chloroquine salts*.—The hydrochloride is given intramuscularly in dosage of 200–300 mg. of base (supplied in ampoules in aqueous solution), repeated in 6 hours if necessary; and intravenously, 400 mg. of base in 500 ml. normal saline by intravenous drip over a period of 1 hour. The sulphate supplied in 5 ml. ampoules (40 mg. base to 1 ml.) is given, in dosage of 200 mg. base intravenously, repeated after 8 hours if necessary.

RADICAL CURE OF VIVAX AND QUARTAN MALARIA

(i) *Pamaquin naphthoate* 8–10 mg. base t.d.s. for 10–14 days. Or

(ii) *Primaquine diphosphate* 15 mg. base daily for 14 days, or 7 mg. thrice daily for 14 days.

During an overt attack a course of treatment with a schizontocidal drug must also be given. This applies also when falciparum malaria is associated with either a vivax or a malarie infection. Some authorities include treatment with a schizontocidal drug even though no active symptoms are apparent.

Careful supervision is necessary over patients taking any of the 8-aminoquinoline drugs, because of the occasional unpredictable occurrence of acute intravascular hæmolytic with or without hæmoglobinuria.

NOTES

Each 261 mg. tablet of *amodiaquine dihydrochloride dihydrate* salt contains 200 mg. of base.

Each 250 mg. tablet of *chloroquine diphosphate* salt contains 150 mg. of base.
 Each 200 mg. tablet of *chloroquine sulphate* salt contains 150 mg. of base.
 Each 100 mg. tablet of *mepacrine hydrochloride* contains 79 mg. of base.
 Each 375 mg. ampoule of *mepacrine methane sulphonate* is equivalent to 300 mg. of *mepacrine hydrochloride*.
 Each 18 mg. tablet of *pamaquin naphthoate* or 10 mg. tablet of *pamaquin dihydrochloride* contains 8 mg. of base. For practical purposes 2 naphthoate = 1 base = 1 *dihydrochloride*.
 Each 15.2 mg. tablet of *primaquine diphosphate* contains 7.5 mg. base.
 Each 100 mg. tablet of *proguanil monohydrochloride* contains 87 mg. base.
Pyrimethamine is prescribed in the form of base, not as a salt.

Reconstruction

AN EXPERIMENT IN FAMILY PRACTICE WITHIN THE NATIONAL HEALTH SERVICE *

F. CHARLOTTE NAISH
 M.A., M.D. Camb.

DURING the past 6½ years I have been adding "extras" to my general practice in an attempt to make it truly a family practice;

The practice is mainly urban. 80% of the births are attended by me or my partner, either in the mother's home or in nursing-homes. An antenatal clinic is held at a separate time from the ordinary surgeries and the mothers are encouraged to attend monthly or at shorter intervals. During the past 2 years my partner has held a relaxation class once a week at which she gives instruction in antenatal and postnatal exercises; most of the primiparæ and a few multiparæ attend. Once a week we hold a clinic for mothers and babies only. A health visitor employed by the local authority attends to weigh the babies, and her advice is useful in sorting the cases for consultation. Before this the mother and baby (hospital cases as well as our own) are visited at home, and the baby is weighed with portable scales. It is usually sufficient to visit twice in the third week and then once weekly to the sixth week. Birth-control advice is offered at the postnatal examination, and, if it is wanted, the mother returns at an appointed time in the evening when she can leave the baby at home. She buys her own appliance, but no charge is made for the fitting and for the advice given.

For 4 years there has been a well-attended mothers' club, and a smaller, but equally enthusiastic, fathers' club. Here an attempt at health-education in its broadest sense is made and the talks and discussions have covered a wide range from infant care to juvenile delinquency. Here also the mothers are taught the early signs of illness, when to send for the doctor, how to nurse a sick child at home, how to prepare a child for admission to hospital, what a child-guidance clinic is for, and much else which improves the mother-child-doctor relationship. The fathers discuss many topics arising out of their

* From a lecture delivered at Oxford (Medical Consilia) on Oct. 15, 1953, and before the Caernarvonshire Pædiatric Club on Oct. 22, 1953.

Year (July-July)	Population of practice	Children under 11 years	Births	Birth-rate per 1000 patients	Birth-rate for York	Admissions of children under 11 years to hospital							Deaths under 1 year	
						Casualty	Surgical	Tuberculosis	Tonsils and adenoids	Medical				
										1	2	Total		%
1948-49	3500	530	58	16.6	18.4	8	1	6	1	12	13	2.6	0	
1949-50	3450	570	58	16.8	17.3	1	7	6	5	4	9	1.6	1	
1950-51	3350	625	62	18.5	15.8	3	3	1	3	2	5	7	1.1	
1951-52	3280	690	67	20.4	14.6	5	4	2	2	4	6	0.9	1	
1952-53	3200	760	72	22.5	14.2	3	5	1	3	1	2	3	0.4	

particular home problems and the wider issues of good citizenship. In doing so they get a better view of the mothers' difficulties and learn how they can enjoy giving help with the family problems.

It would seem obvious that such an attempt at family practice should give good results; but those results are hard to measure. How can one measure health? How can one measure the mental good-health of a family as a whole?

It occurred to me that there was at least one measurable index, and that was the non-admission to hospital of children with medical complaints which could be treated at home.

In the accompanying table, patients under "medical 1" were admitted as medical cases: those under "medical 2" were admitted as query-surgical cases and the diagnosis was proved incorrect.

Other notes on the table are:

1. Among the casualties admitted there was not one case of burns or scalds.
2. The tuberculosis cases consisted of two patients with mild general symptoms and positive Mantoux tests and a third with tuberculous meningitis, who recovered. (He reached hospital 5 days after the onset of malaise.)
3. The following are omitted from the table altogether:
 - (a) Three inevitable deaths (one leukaemia, one aplastic anaemia, and one sarcoma).
 - (b) Six cases of poliomyelitis (no deaths).
 - (c) All fever-hospital cases. All these were cases of scarlet fever, and admission to hospital was determined by the father's occupation, not by the wish of the mother or doctor. Where the father worked with food, home nursing was not allowed.
4. Of the infants who died, three were premature babies under 3 lb. in weight, two of these being twin births. All these were born in hospital. The fourth death was from whooping-cough in a twin of 7 weeks, birth-weight 5 lb.
5. The birth-rate has risen during the 5 years, and the number of children under 11 has risen apart from the increase by births. The practice population, on the other hand, has fallen, mainly because of re-housing on outlying estates and because of the N.H.S. "purge" of lists.
6. The number of children under 11 (this arbitrary limit has been chosen because I have been in York 11 years) is perforce an estimated figure. No practice is ever static, and in a period as long as 12 months there is considerable movement of people. The average for the year has therefore been estimated; but the estimate (checked by two methods) is, I hope, fairly reliable.
7. For each year the expected number of infant deaths, calculated from the infant-mortality rate of the city, is between 1 and 2. So the actual deaths do not suggest that the reduced admissions to hospital have involved any added risk to the infants. Apart from the inevitable deaths mentioned above (3a) there have been no deaths among children more than a year old.

CONCLUSION

I think it would be fair to conclude that there have been some gains to the child patients. It would appear that their mothers are growing more capable of sending for the doctor in the early stages of illness, when the

condition can be treated at home, and also that they are managing to nurse them at home effectively.

To the doctor there appears to be a loss, at least as far as the first 5 years show. I have done more work than the N.H.S. demands, without increase of income. It may be that this work will pay a good dividend in healthy families in the future, but it seems unlikely that an unenthusiastic doctor would take it on without some financial inducement. As the duty of paying a doctor for preventive services rests at present on the local authorities, the Ministry of Health will naturally hesitate to offer such an inducement the cost of which will fall on the general medical services.

The Widdicombe File

XII. DOWN IN THE REGION

Underwater Hospital,
Underwater.

DEAR SIR DANIEL,

I am sending you, as you request, a summary of our findings in John Jones, aged 3. Biopsy shows that he has a Wilms tumour with extensive secondaries, and is beyond our aid. His end cannot be far off, and I only hope it gives his parents some comfort that he should die in a teaching hospital rather than with us. Mrs. Jones took him out of Underwater against our advice, and was rather unpleasant about the whole thing. She is convinced that you will know some new treatment that we have never heard about, and in her distraction I can forgive her anything; but she is only an example of an attitude of mind that is quite widespread down here. It is simply that when we cannot give a good prognosis and assure a rapid cure, the children are removed to London. Even if we offer them a second opinion they refuse it, for their one object is to get the child under a London consultant and be shot of us. Of course our diagnoses are sometimes wrong, and even more often we are completely foxed, but I find these are the cases we ourselves refer to you, and we are grateful for your help.

There is no mystery why parents do these things, and who can blame them if you and your hospital are famous and we are not. Lack of fame is not necessarily synonymous with ignorance or incompetence, but the public nevertheless believes that nothing later than Hippocrates has percolated down our way. Maybe there is an element of truth in it, but I am certain it is not the whole explanation, which is much more fundamental. Unfortunately we work in hospitals with a past, and we suffer a visitation of "the iniquity of the fathers upon the children unto the third and fourth generation of them that hate me."

* * *

Before the National Health Service started, the hospitals now administered by regional boards either were voluntary or belonged to the local authority. The former certainly had the voluntary spirit, and radiated the local pride which kept them going; but the staff were mostly general practitioners, and the ancillary services such as pathology and radiology not infrequently somewhat primitive. They could and did deal perfectly adequately with the routine stuff, but anything more difficult was sent to London. The local-authority hospitals lacked not only the voluntary spirit, but only too often the human touch as well. They had their origins in "The Workhouse"; and as a matter of fact the older inhabitants round here still refer to Underwater as "The Union." With the passage of time, the medical work grew and the workhouse shrank; so the name was changed from workhouse to hospital; but just as when the Rat-catcher became the Pest Officer, the change of title made no difference to the function. These so-called hospitals were managed by the public-assistance depart-

ment with its poor-law outlook; and though later on (in our case very much later on) the public-health department took over, they had neither the time nor the money to do much about it.

I first came to Underwater in 1939 with the E.M.S., and to one who had been nurtured in the gentle atmosphere of a teaching hospital it was horrifying. The buildings, with few exceptions, were bare and barrack-like, with the patients crowded in to overflowing. The nursing staff was insufficient and inefficient, and the male orderlies both callous and brutal. One sensed that the inmates were there to die and were expected to coöperate by not taking an unconscionable time about it. Can you wonder that its reputation stank for miles around, and that nobody would go there until he was unconscious or too weak to protest?

The E.M.S. changed all that, and the N.H.S. has improved things even more. The buildings were modernised and equipment flowed in. The original nursing staff departed in toto, without mourning or regret; and, though we are still desperately short of nurses, what we have are not bad. The medical staff, which in 1939 consisted of five general-duty officers, is now fourteen consultants, all properly qualified and trained, and ten residents. We have fewer patients to care for than in the bad old days. The pathological side of our service could and should be improved; for, though the quality is excellent, the quantity is too small. In London you have bacteriologists, biochemists, hæmatologists, histologists, and morbid anatomists, each with assistants and technicians, whereas at Underwater there is one pathologist and a few technicians who have to cope with all our work. This staff must be increased, and I hope that nobody will try and substitute an area central laboratory in its place. Such an institution is like a sausage-machine, with material going in at one end and results emerging at the other; and the results, like sausages, are often of dubious quality. We must be able to discuss our problems with the pathologist, so that both sides can know the extent of their limitations. This is particularly important in pædiatrics, where biochemistry now looms so large; but Underwater is like Hamlet without the Prince of Denmark, for no biochemist walks our stage.

The deficiencies I have mentioned are fortunately not crippling, and in spite of them we are both competent and equipped to deal with most of the problems that confront us. We should have gained the confidence of our patients, and to a large extent we have; but memories of the past still lurk in too many minds. The public is not to blame, because nobody has ever told them of the changes that have been brought about in their hospitals. They can see the new chairs and the canteen in outpatients, but how are they to know the ability or training of Dr. A as compared with Dr. B? They cannot judge whether an X-ray film is good, bad, or indifferent—much less the value of the radiologist's report on it—and the whole working of the pathology department is entirely outside their ken. I think it would help if they were enlightened on these matters.

* * *

If then our need is publicity and propaganda, no opportunity is lost to see that we don't get it, and in fact the only time we are likely to get in the news is if somebody brings an action against us for negligence or some cataclysmic disaster befalls us. Our day-to-day work is unknown. Take television as an example. There have been two programmes depicting hospital life—both of them to my mind nauseating, but let that stand. The important thing is that they featured teaching hospitals, when one of them at least could have dealt with Underwater. On another occasion there was a film showing a coloured nurse undergoing her training at the Middlesex Hospital, afterwards returning home to

disseminate her knowledge. This was grossly unfair, because I am sure that most coloured nurses don't train at teaching hospitals, and if you met one in Central Africa she would more likely be familiar with Underwater than the Middlesex.

Another thing that would help us would be some visits from V.I.P.s. The press notices and photographs that go with them catch the public eye, and they rightly feel that a hospital worthy of such a visit can't be too bad. I do not forget that we ourselves must take a hand in the matter, and not expect everything to be done for us. My one experience in this line was quite encouraging, for I managed to get a small article and a photograph of one of our patients in a national daily. Quite a lot of local people saw it, and subsequently some of our ex-nurses and residents sent us reproductions that they had cut from their local newspapers in Australia, South Africa, Germany, and South America. I admit that this is only small stuff, and that for a major effort we shall require the help of the Ministry of Health; but, as they have nothing to be ashamed of, they shouldn't be too difficult to stimulate.

Do you think we could make this a coöperative effort?—because so far the teaching hospitals have been ivory towers, with little knowledge of what goes on around them. Our professional lives are widely affected by advice given and decisions made by the teaching hospitals, and we would accept this more readily if we thought you knew a little more about us.

Yours sincerely,

JAN STEWER.

Parliament

QUESTION TIME

Home Care of Aged

Sir WALDRON SMITHERS asked the Minister of Health if, in view of the high cost of maintenance of old patients in hospitals and of the shortage of nurses, he would consider the advisability of setting up a committee to inquire into the practicability of making an all-in payment to relatives or friends willing to take chronic cases into their homes.—Mr. IAIN MACLEOD replied: I do not think it would be feasible to introduce arrangements of the kind contemplated. Apart from the fact that sometimes it would not be in the interest of patients to be cared for at home, there is already provision whereby, in suitable cases, financial assistance could be sought from the National Assistance Board.

W.H.O.'s Budget

Replying to a question, Mr. MACLEOD said that the proposed increase in the World Health Organisation budget involved additional expenditure of about 1,800,000 dollars. The United Kingdom delegation was authorised to agree to an increase of about 1 million dollars but to oppose the further increase on the ground that it was attributable to projects which should be financed through the expanded programme of technical assistance.

Pay Beds

Replying to a question, Mr. JAMES STUART, Secretary of State for Scotland, said that about a quarter of the hospital beds for private patients in the Scottish Western Region were unoccupied, on the average, during the latest period for which figures were available. This represented about 100 beds scattered over 33 hospitals. He did not think that 100 beds vacant in 33 hospitals was a large number. There were always gaps whether for paying or non-paying patients between the discharge of one patient and the admission of another.

Dentists in the Forces

Replying to a question, Mr. E. N. C. BRICH, parliamentary secretary to the Ministry of Defence, said that 512 qualified dentists were at present serving in the Armed Forces—97 were in the Royal Navy, 250 in the Army, and 165 in the Royal Air Force.

In England Now

A Running Commentary by Peripatetic Correspondents

I AM no good at gardening but I do enjoy trimming my privet hedge; for this humble occupation gives me a chance to turn philosopher. My hedge, with its uniform structure, its growth and decay, its activity and rest, its stability and change, is not unlike society. For instance, this cheeky twig, overtopping his fellows, reminds me of the human unit who shoots out his neck and tries to get the best of everything. Here is the woman who jumps the queue; the arrogant, flamboyant man who has got on; the nasty kid who is always shouting "Me first"; the aggressive, swaggering individual that no one can curb. Here to my hand are the bombast, the snob, the upstart, the cheat. Snip, snip, go my shears; and heads drop around me in my gigantic purge, giving the hedge a mathematical seamliness and my soul an artistic satisfaction.

"But," occasionally says my better self, "that may be a genius and should be preserved." Then I have an argument with myself, generally coming to the conclusion that genius is so rare that it is most unlikely to be found in any social structure or privet hedge of my acquaintance, and that my first diagnosis of swanky selfishness has more chance of being correct. In any case, a genius usually fills a gap, and is never quite the saucy twig I have in mind but rather the strong, resolute shoot which, in the old days, our forbears left here and there in our country hedgerows to greet us now as tall, well-spaced trees.

"But what about back pruning?" you may ask. Of course I haven't forgotten that. All too well I know the chunks of dead wood and the dead-alive branches that keep interfering with the clamant new growth, twisting and deforming active twigs into roundabout ways and leading to the deterioration of the hedge. Their social counterparts are the miserly curmudgeon of an old man; the enslaving, demanding old woman; the frustrated "youngsters" of 45 and more whose lives have been given up to mum and dad. Snip, snip, go my secateurs; for it is a tricky job dealing with the aged things that in their day contributed to the hedge which is now my delight; and I have abandoned the shears for more kindly treatment. Here one must ever be careful not to injure the solid living wood that gives to the hedge its substance and permanence—the wisdom and stability of its long heritage.

"But what a terribly uniform, uninteresting society you are going to make," you may say. Well, perhaps you're right. But I've got a jolly nice hedge.

* * *

"Where are the children?" asked my wife. "I left them in the department in the animal house. There are some new baby rabbits. I expect they will be back in a few minutes" I answered. But the minutes ticked on to something over an hour. "I wish you would go and see what they are doing, it's getting dark and they may be frightened."

Recognising the finality of the situation, I got up and went across to the department. The noise of my footsteps going up the stairs was an "indifferent stimulus" for the conditioned response of the guinea-pigs, and I opened the door of the animal house to a crescendo of squeaks. The children were not there.

Down the stairs again and I switched on the lights in the museum. Still no sign of them, but I could hear them. Quietly I looked into our long dissecting-room. There they were: George (11) and Catherine (10), the light on over a table, white sheet turned aside. "Don't be silly, George, the heart is not down there, it's up here." Catherine was always the quick one. "What's this, then?" asked George. From the distance it looked like the spleen. "I don't know. Do you think this is the liver? It's not like the liver Mummy gets from the butcher, it's hard." I walked over and sat down beside them and told them about the contents of the open abdominal and thoracic cavities.

Dislike for the "dead" does not appear to be an inherited characteristic. The female tremor of distaste and the hearty male laugh—symptoms of the adult taboo—are obviously an acquired reaction. Is it wholly

mimetic, simply a convention; or has it deeper roots as far back as our troglodytic ancestors who initiated the practice of burying their dead?

Sarah Milicent Brown lived in a small, terraced house, in a grim and sordid suburb of a northern city. She was cared for by an only daughter who was an albino, and who had been given, by some waspish twist of fate, the name of Blanche. This poor girl, who could not bear the light, moved about the darkened house like some pale spectre of the night. When I saw the old lady for the first time in 1933, she had already been bedridden for five years following a stroke which had left her paralysed.

She was in perpetual dread of draughts. The window of her bedroom was permanently closed and the heavy curtains drawn. The chimney was blocked by a mass of crumpled paper, and a small tongue of leather was attached to the key-hole to stifle the piping of the wind. Heat was supplied by a fuming oil-stove and light by a bracketed gas-jet, which spluttered fitfully in the choking atmosphere and did little more than trouble the gloom.

When I opened the door on my first visit, it took me some time to accustom myself to the dark, but as soon as I could see I went over to the curtains and drew them aside. For the first time in five years daylight flooded the bedroom. And then I threw open the window and took a long breath. Sarah Milicent Brown eyed me from her bed with a look of intense dislike and, in a voice surprisingly firm for an invalid, commanded me to shut the window at once. I was about to protest when Blanche, who had followed me silently into the room, slipped behind me and brought the window down with a bang as though the air outside had been thick with contagion. I realised I had committed a grievous offence, and it took me two years of patient visiting to regain the old lady's favour—two years and many more to follow with the curtains drawn and the window tightly sealed.

On the night of Nov. 5, 1953, the noise of fireworks in the street had made her fretful and sleepless, and Blanche had called me in to give her something to calm her down. I was groping around in my bag for my syringe when she leaned over and plucked at my sleeve and said:

"What kind of a night is it?" It was the first time I had known her to inquire about the world outside her room. "Dark and foggy—you're better here in your bed." I thought she smiled—but in the dim and lurid light it was impossible to be certain.

"You may open the window, now, doctor."

I drew the curtains slowly and hesitated; but she nodded approval, so with difficulty, for it was stiff with disuse, I forced the window wide open. A thin November fog, acrid with the smell of gunpowder, trailed into the airless room. And when I turned round she was dead.

REACTIONS OF A MORBID ANATOMIST TO MAKING THE ACQUAINTANCE OF THE KAUFFMANN-WHITE SCHEME

I'm sure when White and Kauffmann wrote their Salmonella scheme They little thought that they'd composed the poetaster's dream.

Who minds anaerogenesis or antigenic loss?
There's consolation in the sound of names like *Hvittingfoss*.

While *morehead* dreams of *poona*, with *havana* and *champaign*,
I drive *uphill* from *nottingham* with *thompson* in the rain.
We'll stop and have a *worthington* in *shipley* on the way
We'd have made it a *manhattan* had it been a *desendai*.

My *mission* will require me fly out to *kaapstad* soon
By *napoli* and *cairo* through an *equatorial* noon.
Mendoza, old *hidalgo*, will put on his *panama*
And join me in *nairobi*—then it 'sn't very *pharr*.

Aunts *adelaide* and *berta* will enjoy the *eastbourne* sun
An *infant* is quite happy with *banana*, *ball* and *bun*.
Let *hindmarsh* take *madelia* in his *austin* to *Dunoon*,
But give me *loma linda* and a *pensacola* moon!

Before the *Salmonella* lose their eponymic names
(*Way cross* the wide *missouri* and to *georgia* away!)
Ere Arab numerals replace the Roman ones, who blames
A *london* salmonellologist who *sanga* little lay?

Letters to the Editor

RAUWOLFIA IN HYPERTENSION

SIR,—The search for hypotensive drugs of low toxicity, and especially for those which are effective when given orally, has given rise to considerable interest in alkaloids from the root of *Rauwolfia serpentina*. Reserpine has been shown to have such a hypotensive action. The most recent communications, by Dr. Doyle and Professor Smirk, and Dr. Joiner and Dr. Kauntze (May 29), prompt me to send this note on results obtained in a small series of hypertensives.

Twelve patients suffering from chronic benign hypertension have been treated with reserpine ('Serpasil'). All were known to have had symptoms of high blood-pressure for five years or more. All presented secondary cardiovascular changes. In two there were retinal hæmorrhages and exudate. The lowest blood-pressure recorded after a week's rest was 210/120 mm. Hg, the highest 250/160.

Each patient was kept in bed for the first week but allowed up for visits to the lavatory and bath. No restrictions were placed on diet. No drugs were given except for constipation or insomnia. The blood-pressures were recorded not less than four times daily, and if a daily variation of more than 20 mm. Hg systolic or 10 mm. Hg diastolic occurred during the last two days of the week, treatment was postponed until greater stability was established. Once it was started the patient was encouraged to lead a more active life, walking about the ward or in the grounds of the hospital.

At first the makers' recommended dose of 0.25 mg. four times daily was given, but it was soon apparent that no hypotensive effect was thereby achieved. Subsequently the amount was raised to 1 mg. four times daily, and, if ineffective, this quantity was doubled. In only one instance was as much as 16 mg. daily given. This dose had to be abandoned on account of dizziness and drowsiness unaccompanied by an appreciable fall of blood-pressure.

As to results, in two patients no effect on hypertension was produced by 16 and 8 mg. doses daily. In a further two a daily dose of 4 mg. resulted in a sustained reduction of systolic pressure by 30–40 mm. Hg and of diastolic pressure by 10 mm. Hg. The remaining eight patients required 8 mg. daily to achieve this or greater effect.

By far the most striking result is to be seen in the systolic pressure readings. A heart-rate of between 50 and 60 is usually noted within 3 days after treatment is started. There is no relationship between the slowness of the heart and the effect on blood-pressure.

Drowsiness and dizziness affected all patients on 8 mg. daily, but passed off in some after a few days. Of the twelve cases two developed pronounced tremor within 24 hours when the dose was raised from 4 to 8 mg. daily. This was of coarse type, accompanied by occasional twitching of the limbs, chattering of the teeth, and mental distress. On halving the dose the tremor disappeared. I have not encountered the pruritus described by Joiner and Kauntze.

It seems probable that reserpine will be of some value in the treatment of benign hypertension, but close supervision is needed. It is possible that lower doses in conjunction with other hypotensive drugs will be more effective. This is being studied. For the intelligent patient no substitute has as yet been found to equal hexamethonium bromide, self-administered parenterally.

London, W.1.

A. H. DOUTHWAITTE.

ARTHROPLASTY v. ARTHRODESIS

SIR,—I am not at all sure what Mr. Norman Capener is getting at (June 19). Apart from his unhappy reference to insults and stigmata, which can safely be ignored, he admits even more strongly than I did the failure of many arthroplasties of the hip-joint, but without being willing to consider one obvious source of failure—namely, that the good idea of surgical reconstruction of a mobile and painless hip has often failed because of imperfect technique: "it was not that the operation was bad but that it was done badly" (June 12). His reply seems to be that the operation should not have been done at all.

We all know that 'Vitalium' cups have seized in the acetabulum, or been stuck on the neck of the femur—to our chagrin it has happened to all of us. We all know that free excisions of the femoral head, or even the femoral neck as well as the head, have been vainly replaced by prostheses which soon worked loose—and we should have known this from the beginning. If we know these things why do we not say them? Are we to be deterred, as has been suggested, by the fear of litigation? Are we not to write to *The Lancet* lest a solicitor reads our letters? If this is to be so we had better abandon all ideas of surgical progress and bask in safe mediocrity.

I for one will go on saying that hitherto the failures of arthroplasty of the hip-joint have very often been the consequence of failures of technique. If we pay more attention to the intelligent thought and precise technique of Fitzgerald in one type of operation, and of Crawford Adams in another, the next review of 500 cases after five years will be very different from the last.

It seems odd that I should find myself defending arthroplasty of the hip-joint, because the whole purpose of my letter of June 12 was to reiterate the belief I have held for many years that arthrodesis is best for mono-articular arthritis in all young patients up to the age of 60-odd years.

London, W.1.

REGINALD WATSON-JONES.

SIR,—I am unable to resist some comments on the statements by Sir Reginald Watson-Jones (June 12) that "there is no difficulty whatever in securing sound arthrodesis of the hip-joint . . .", and that "if a surgeon wants to arthrodesise a hip-joint he can always do so."

As one who believes ardently in arthrodesis of the hip-joint, I am in complete agreement with Sir Reginald regarding the excellence of hip fusion in unilateral disease. It is a great pity that patients cannot more easily be made less horrified at the first suggestion of "having the hip stiffened," and it is a pity that the general public cannot know the disappointments hidden in the attractive-sounding operation of arthroplasty.

But to suggest that the painful hip can *quite easily* be got into the idyllic state of osseous union is certainly not the experience of most orthopaedic surgeons. If arthrodesis of the hip by standard methods were a trouble-free procedure recent exponents of arthroplasty would have had to face much more serious competition than has been the case. In osteo-arthritis (malum coxae senilis), where the bone is often densely sclerosed and where the leverage of the long shaft of the femur is immense, the hip is still the most difficult joint to fuse of any in the whole body. Stinchfield and Cavallaro¹ found that in 58 cases of osteo-arthritis 26% failed to achieve osseous union (and presumably therefore had to face a second operation). 10 cases of this series showed delayed union and required prolonged fixation, which means (my own calculation from their figures) that 43% did not proceed according to the plan that the surgeon had predicted when advising these patients to submit to the procedure. One can

fairly safely assume that this 43% must have lost permanently a considerable range of movement in their knees.

The fact is that the patient with a failed arthrodesis (by orthodox techniques) is in almost as pitiful a state as one with a failed arthroplasty. The only way a patient can cope with an arthrodesed hip is by virtue of a fully mobile knee. A stiff hip and a stiff knee is a calamity. So many surgeons have realised this that they have shown sound surgical judgment in deliberately choosing an imperfect arthroplasty, giving partial relief in a short time, rather than to risk the possibility of being landed with the long-drawn-out horror of a failed arthrodesis.

The technique of central dislocation of the hip which I advocate² guarantees full knee movement because the knee is fixed for only four weeks. But even by the central dislocation technique I have never evaded the frank admission that osseous union is possible in only about 75% of the older patients with osteo-arthritis. The almost uncanny feature of this operation, however, is that the ability to bear weight without pain is just as good when it is a fibrous ankylosis as when osseous. This is a statement which may appear exaggerated and irresponsible to surgeons accustomed to identifying fibrous ankylosis with failure. It would seem that fibrous ankylosis is painful after "orthodox" attempts at hip fusion because the hip is potentially unstable if osseous union fails and the fibrous union is thereby subjected to stretching forces. If osseous union fails after central dislocation, the hip still has greater stability than before operation, because a bone-block is present to sustain the weight of the body and the fibrous union cannot therefore be stretched.

By the central dislocation technique, as I use it in elderly patients with osteo-arthritis, the average stay in hospital is about eight weeks. At the end of this time they are able to look after themselves at home, do not require any form of physiotherapy whatsoever, and use a stick only during the first three or four months while regaining balance and confidence. This procedure of stabilising the hip and removing pain has many features in common with the displacement osteotomy of McMurray, but has important advantages in the shortness of the postoperative programme.

Department of Orthopaedic Surgery,
Royal Infirmary, Manchester.

JOHN CHARNLEY.

IS HYPERTENSION A DISEASE?

SIR,—With reference to your leading article of June 12 I would like to make some observations and ask some questions based on my experience in general practice:

If disease means difficulty at being at ease, then hypertension is certainly a manifestation thereof.

If the western half of civilisation is hypertensive, then why not study the "abnormal" persons among us to get some idea of how to rearrange our existence to keep what is good and remain healthy?

Renal studies have shown a mechanism of producing hypertension. What about an equivalent, though apparently different, mechanism in other organs? For example, what diminution of blood-flow is to the kidney so could lack of exercise be to the extracellular electrolyte distribution; or could hypertension be an attempt to increase the hydrostatic element to compensate for disturbance of the electrolyte pattern brought about by dietetic and/or endocrine imbalance?

If genetic inheritance is important then we cannot do a great deal about it unless we start selective breeding. (Or are we unwittingly selecting factors which carry with them diminished reserve to stress?) Why not consider "environmental" and/or "familial" inheritance as a pattern?

Awareness of hypertension seems to play a major part in the production of symptoms, but how many people have the symptoms of hypertension (if any) without an increased blood-pressure?

Can we study hypertension per se, or should we not study the pattern of abnormal reactions to stress in general? (For

1. Stinchfield, F. E., Cavallaro, W. V. *J. Bone Jt Surg.* 1950, 32A, 48.

2. Charnley, J. *Compression Arthrodesis.* Edinburgh, 1953.

instance, a hypertensive in one generation may have as an equivalent a thyrotoxic in the next; or an ulcer patient may have an accident-prone brother or a bankrupt uncle.)

The reason I put forward these jottings is that when, as now, we are floundering for a better understanding, this can often be achieved by reorientating what we already know.

Clapham, Lancashire.

J. A. FARRER.

EFFECT OF CONTROLLED HYPOTENSION ON CEREBRAL FUNCTION AND CIRCULATION

SIR,—Dr. Saunders (June 5) compares his $(A-V)O_2$ difference results during hypotension under anaesthesia with those in the non-anaesthetised subject. We feel his results should be compared with those in subjects under similar anaesthetic conditions without hypotension.

Hestates that the cerebral $(A-V)O_2$ difference represents the ratio of the cerebral metabolic demand to cerebral blood-flow. This is so, and the $(A-V)O_2$ difference varies inversely with the ability of the cerebral circulation to cope with the metabolic needs of the brain. Kety's figures¹ show the $(A-V)O_2$ difference to be 3.7 vols. % under anaesthesia. Thus Dr. Saunders's figure of 4.8 vols. % is an increase, and shows a decreased ability of the cerebral circulation to cope with the O_2 requirements of the brain.

Dr. Saunders uses Kety's figures for cerebral metabolic rate under light ether anaesthesia. These figures are based on the cerebral blood-flow obtained under light ether anaesthesia with normal blood-pressures. In Dr. Saunders's cases the blood-pressure is far from normal, and thus quite possibly the cerebral blood-flow may be changed—which is in fact suggested by the increased $(A-V)O_2$ difference.

This increased $(A-V)O_2$ difference may be sufficient to compensate for the decreased blood-flow through the brain and thus leave the oxygen uptake unchanged. Dr. Saunders is unjustified in assuming that the metabolic rate of the brain is the same under his hypotensive conditions as under normal anaesthesia, unless this is proved to be so by estimating the cerebral blood-flow under these conditions (i.e., estimating cerebral blood-flow under anaesthesia before and during the hypotension, thus ensuring that cerebral metabolism is unchanged).

We have done this.² Although we employ a 10° head-up tilt our level of hypotension is not so low as Dr. Saunders's—an average systolic pressure of 70 mm. Hg is obtained, and with this figure an average drop of 30% in cerebral blood-flow has been found by Kety's nitrous-oxide technique.¹

This drop in cerebral blood-flow does not appear to be dangerous since the $(A-V)O_2$ difference (average 5.5) increases sufficiently to give the same figure for cerebral metabolism under these conditions of hypotension as in the controls under normal anaesthesia.

Department of Anaesthesia,
University of Liverpool.

GOUGH HUGHES
H. RIDDLE.

SIR,—Dr. Enderby has done much to champion the valuable technique of controlled vascular hypotension, but his letter of June 19, referring to Dr. Saunders's paper, contains an assumption which may be dangerous if taken at its face value.

Dr. Saunders was careful to place the limits of safety of controlled hypotension at 55–60 mm. Hg systolic “when the patient is kept horizontal or nearly so,” but Dr. Enderby has gone further and inferred the safety of cerebral arterial pressures appreciably lower than this. In my view, there is no satisfactory experimental evidence that these low levels are safe, and the hints we have suggest that they are not. Experimental work in

this field is extremely difficult, bedevilled as it is by varying cerebral oxygen consumptions in the conscious and anaesthetised states, but electro-encephalographic evidence in the conscious subject supports the view that 55 mm. Hg systolic is a critical level in healthy persons.¹

Griffiths has pointed out an added danger in the tendency to a fall of blood-sugar during administration of methonium.² With a respiratory quotient of 1.0 and absence of carbohydrate reserve, the brain is intolerant of hypoglycaemia, and unlikely to survive the combined insults of extreme hypotension and nutritional insufficiency at the same time.

Recently my own (unpublished) findings with total oxygen consumption show that an over-all oxygen debt is incurred at pressures below 55–60 mm. Hg, under light general anaesthesia, and the debt is discharged when the pressure is restored to higher levels. While the brain cannot incur an oxygen debt (it would rather die than do so), the presence of a debt at all indicates the existence of vascular insufficiency somewhere in the body.

Controlled hypotension is of great value in saving blood-loss and operative time; but we must insist that our limits of safety err on the high side, and as far as possible are based on experiment and not assumption, or disasters will follow and a useful technique fall needlessly into disrepute. A considerable portion of the brain can be destroyed without gross disturbance, but few of us would care to risk our higher faculties under profound hypotension, even in the interests of economy.

Emsworth.

P. R. BROMAGE.

PATHOGENESIS OF RHEUMATIC FEVER

SIR,—Dr. Coutu, of Montreal (June 12), criticises conclusions reached by me in the Milroy lectures of 1954 (*Lancet*, March 13). He is correct in saying that I “question the relevance, for human beings, of experiments performed on rats.” In fact, I go further and question the relevance to human beings of experiments performed on any animal. The prospects of relevance to human beings increase as the strength of the analogy between a given species of animal and man increases. On this basis, in my particular argument, the guinea-pig provides a stronger analogy than the rat.

Dr. Coutu is also correct when he says that I question the application of Professor Selye's views to rheumatic disease. Professor Selye showed that adrenocortical activity is readily stimulated in the rat by comparatively mild forms of “stress”—a phenomenon associated with involution of lymphatic tissue, ulceration of the gut, and hypofunction of the other endocrine glands. If such an easily detected phenomenon occurred in man, it is strange that it has not been described as a postoperative complication. Stress can precipitate an attack of rheumatic fever or rheumatoid arthritis, but it does not follow that a syndrome analogous to the rat adaptation syndrome is responsible.

Dr. Coutu is again correct in saying that I question not only the application of Professor Selye's views but his use of the term “antiphlogistic,” which I consider meaningless and therefore confusing. I shall attempt to clarify the issue. In my hands, cortisone effectively depresses slowly developing allergic lesions of the tuberculin type, but is without effect on the size of inflammatory lesions resulting from the intradermal injection into guinea-pigs of various bacteria and/or of exotoxins. I conclude that the anti-allergic activity of cortisone in this particular creature cannot be attributed to a general anti-inflammatory action. A comparable experiment in man³ produced a similar result. It is likely, therefore, that the anti-allergic action of cortisone

is so much greater than the anti-inflammatory action that if the latter exists its rôle in man and therapeutic significance is likely to be slight.

Dr. Coutu is confused by the term "antiphlogistic"; he provides a list of 22 references to support his contention that cortisone exerts an anti-inflammatory action. Of these, 9 are devoted to the anti-allergic action of cortisone and 7 to the effects not of cortisone but of corticotrophin. It is easy to select references to show that cortisone exerts remarkable effects which do not occur in my laboratory, but a mass of reports will not fill the rôle of a single convincing paper.

Dr. Coutu provides an excellent example of the difficulties in obtaining first-rate evidence. He worked on the effect of corticotrophin on the inflammatory response to mustard powder, and, in spite of the logical and practical objection that corticotrophin and cortisone are not the same thing, questions my work with cortisone. I spent some years working on the influence of corticotrophin on inflammatory responses. I found they were decreased, but only by certain batches of corticotrophin. Such responses bore no relation to the unitage and could not be duplicated with cortisone or with other available adrenal steroids. Moreover, the effects of corticotrophin in the guinea-pig were so transient that I could not distinguish between real and compensating effects. I could not therefore interpret my own results; neither can I interpret his.

SALICYLATES AND ADRENOCORTICAL STEROIDS

SIR,—In your issue of May 15, Dr. Smith and his colleagues and Dr. Bayliss and Dr. Steinbeck discuss the action of salicylates on the 17-hydroxycorticosteroids in man.

As regards the first of these papers, similar work with similar results was described by Hungarian authors in 1952,¹ and by Coste et al.² in France in 1953, using the biological method of Cope.³ The daily excretion of urinary cortisone-active material was unaltered during salicylate therapy.

On the other hand massive doses of salicylate commonly increased plasma 17-hydroxycorticosteroid levels in the patients of Ely et al.⁴ Finally, we have repeatedly suggested that the therapeutic effect of salicylate can hardly be explained in this way.^{1, 5}

TRAVERSING WOUND OF THE HEAD

SIR,—Mr. B. H. Dawson's article of May 22, describing a traversing injury of the head with complete recovery, reminds me of a somewhat similar remarkable case.

In 1946, while serving with the Forces overseas, I was called out one afternoon to see a young soldier who had just shot himself through the head. I expected to find him dead, but instead he was lying on his bed with blood streaming from nostrils and mouth and able to talk coherently. He had been suffering from mental depression for several days and had resolved to commit suicide. He had fired one shot through the open mouth from a Smith-Wesson revolver while lying on his back with his head on a low pillow. After doing this, he was distressed to find that he could get up and walk around the room. He was pale. The pulse-rate was about 90, with poor volume. There was a small circular entry wound in the midline of the hard palate and a larger irregular exit wound in the left parietal region two inches from the midline

and about the same distance behind the coronal suture. There was little comminution of bone, and hæmorrhage was mainly from the nose. He could see and hear normally. I took him several miles over imperfect roads by ambulance truck to hospital, where a careful wound toilet was carried out. The patient made an uninterrupted recovery, and several months later he was well enough to appear before a court-martial. There was no mental defect and no history of post-traumatic epilepsy. All the cranial nerves were functioning normally. It was remarkable that the left optic nerve escaped injury.

As a further illustration of the resistance of the brain hemispheres to trauma applied at right-angles to the skull, I might mention the ancient Chinese practice of passing metal needles through the head to provide an outlet for evil spirits.

CERTIFICATION FOR MENTAL DISORDERS

SIR,—Many of your readers are, like myself, deeply concerned with improving mental hospitals and the care of mental illness; and they chiefly want to know how they can do this with the means at their disposal. Yet, not only do many otherwise well-informed people still seem to regard certification as an essential and inevitable part of psychiatric care, but the great majority of psychiatrists seem to be unaware that certification has been virtually abolished in both Eire and Northern Ireland. To these I commend that masterpiece of humanitarianism, the Mental Health Act (Northern Ireland), 1948.

As a medical journal is hardly the best place for a lay writer to offer medical statistics, I will confine myself to the statement that in the British Isles—excluding Northern Ireland—we have today some 200,000 mental patients certified under an Act which is archaic and should be amended. That the Act is obsolete is evident from the establishment of the Royal Commission, to which it was recently my privilege to submit evidence on this score.

Surely, we—who were first in the field with anaesthetics, antiseptics, antibiotics, and other great advances—must advance also in the field of psychological medicine. For certain, the time has come for us to separate the "insanity" of the law from the "mental illness" of medicine. Let us, therefore, follow the lead given by Northern Ireland and Eire.

FETAL HEPATITIS

SIR,—The following case may be of interest in view of your annotation of June 5.

A 3-week-old infant was brought to this hospital with deep jaundice of 2-3 days' duration. All the evidence pointed to the jaundice being obstructive in origin. The plasma-bilirubin was of the order of 30 mg. per 100 ml. and a 24-hour specimen of faeces was entirely free from stercobilin. The alkaline phosphatase, however, was 8.5 King-Armstrong units. The blood picture was entirely normal, and the Coombs test negative.

Thus bile-duct atresia was diagnosed, and the child was submitted to laparotomy. At operation, however, absolutely nothing abnormal was found. At this stage it was decided to regard the case as one of hepatitis due to umbilical sepsis and umbilical-vein pyæmia,¹ although there was no obvious evidence of either umbilical infection or umbilical pylephlebitis. Aureomycin was accordingly given, and the jaundice regressed rapidly after 3-4 days.

A complicating feature was the development of severe anaemia of aplastic type which reached its height when the recovery from the jaundice was almost complete. At this stage there was still no evidence of hæmolysis or the presence of antibodies, and the anaemia was not considered to be due to the medication, which had been started after the anaemia was first detected. The child received a blood-transfusion,

and since then has not looked back. After the transfusion the thymol-turbidity level rose to 4 units; previously the level had been less than 1 unit.

This case has been regarded here as one of septic hepatitis, but viral infection of the liver may have been the cause of the illness.

CHLORPROMAZINE IN STATUS ASTHMATICUS

SIR,—Status asthmaticus is not uncommon, and it may be fatal.¹ Treatment becomes very difficult when the patient does not respond to antispasmodic drugs—none of which is likely to prove of any value if subcutaneous adrenaline and intravenous aminophylline are ineffective. Sedatives, which relieve mental distress and may also lessen the asthma, may be tried; but a small dose is usually ineffective, and a larger dose may depress respiration to a degree dangerous in an anoxic patient.² We have ourselves seen a young woman die after two 3-grain doses of sodium amylobarbitone by mouth.

The pharmacology of chlorpromazine ('Largactil')³ suggested that it might be valuable. It is said to have a depressant action on the cerebral cortex but not on the respiratory centre. Electro-encephalographic tracings are comparable with those of normal sleep.⁴ Laryngeal and tracheobronchial reflexes mediated by the vagus nerve are depressed, and postoperative secretions are reduced.⁵ In animal experiments capillary permeability is reduced and oedema of mucous membranes is prevented. Chlorpromazine also lowers the metabolic rate.

We have tried chlorpromazine in four cases:

CASE 1.—Mrs. A, housewife, aged 50. Asthma began in 1948, and on Dec. 10, 1953, she was admitted for the fifth time. She was cold, pale, cyanosed and sweating profusely; pulse-rate 160, blood-pressure 160/90 mm. Hg. She was given oxygen and intravenous aminophylline 0.25 g., intramuscular phenobarbitone gr. 3, and oral ephedrine gr. 1; but four hours later (11.30 P.M.) her condition had deteriorated. She was put in an oxygen tent, and at midnight promethazine 100 mg. was given slowly intravenously. She became slightly drowsy and the "spasm" lessened a little. At 12.15 A.M. chlorpromazine 25 mg. was given intravenously. She now went to sleep, her colour became pink and the respirations much quieter; the extremities were warm and the sweating ceased. At 12.45 A.M. the blood-pressure fell to 100/80; at 1 A.M. it rose to 120/90, and, though she was still fast asleep, the expiratory wheezing had almost gone. The pulse remained at 160 throughout (tachycardia is often an effect of chlorpromazine). Next morning she was drowsy but coöperative and the attack had ceased.

CASE 2.—Mrs. B, aged 55, had her first attack of asthma in 1952, and had since been in hospital six times. She was first admitted to Whittington Hospital at 1 A.M. on Dec. 20, 1953, with status asthmaticus of three days' duration. She was cyanosed, with widespread bronchospasm; pulse-rate 120, blood-pressure 180/90. She was given intravenous aminophylline and intramuscular phenobarbitone, but three hours later she was much worse. She was therefore given a combined intravenous injection of chlorpromazine 12.5 mg., pethidine 25 mg., and promethazine 25 mg. She went to sleep and the spasm was relieved though not abolished. Next morning she was drowsy; there were a few rhonchi but no spasm.

CASE 3.—Mrs. C, aged 31, had had asthma for ten years, and in the past year had been off work for four months, with periods in hospital. On Jan. 4, 1954, at 10 P.M., she was readmitted, deeply cyanosed and in great distress; pulse-rate 140, blood-pressure 130/90. Intravenous aminophylline was without effect, so at 10.40 P.M. she was given chlorpromazine 50 mg. She became sleepy and less distressed

and the colour improved; her pulse-rate rose to 160. At midnight she was sleepy but easily roused; pulse-rate 144, blood-pressure 100/80. As there was still some spasm she was given chlorpromazine 20 mg., promethazine 20 mg., and pethidine 20 mg., together intravenously. The breathing improved and the pulse-rate fell to 120; blood-pressure was 100/70. She slept through the night and by morning the asthma had ceased.

CASE 4.—Mrs. D, aged 51, an asthmatic of many years' standing, was admitted on Jan. 4, 1954, at 8 P.M. She was deeply cyanosed, in great respiratory distress and very restless; pulse-rate 100, blood-pressure 100/50. She was given intravenous aminophylline and intramuscular paraldehyde, and was put in an oxygen tent. She remained restless and dyspnoic throughout the night, and at 7 A.M. was given phenobarbitone gr. 3 by intramuscular injection. When seen by us at noon she was semicomatose, restless, and cyanosed in spite of the oxygen tent. She was violent at times and had not been sufficiently coöperative to drink since admission. She was therefore given a combined intravenous injection of chlorpromazine 6 mg. and promethazine 6 mg. very slowly, being restrained for the purpose by three nurses; she fell asleep during the injection. The pulse-rate rose from 120 to 160 but fell again within twenty minutes to 124; the blood-pressure remained steady at 140/100. She slept quietly if not disturbed, and by 9 P.M. she was no longer cyanosed and the bronchospasm was much less though she was still confused and uncoöperative. At 11 P.M., as the effect of the paraldehyde and phenobarbitone had worn off, she was given chlorpromazine 50 mg. and promethazine 25 mg. intravenously. She fell asleep and next morning she was rational and free of the asthma.

In these cases, though the promethazine and pethidine given were probably of some value, the greater part of the improvement appeared to be due to the chlorpromazine, which enabled the patient to sleep without depressing respiration. Relief of bronchospasm was not immediate, and may have been caused as much by the adequate sedation produced as by any direct antispasmodic action of the drug. After the injections sweating stopped, cyanosis was lessened or abolished, and the extremities became warmer. Although there was always tachycardia, the heart's action was not irregular and fall of blood-pressure was only slight and transient.

In our view parenteral administration of chlorpromazine should at present be restricted to the more severe cases; but we have given it by mouth in a few mild cases with some apparent benefit.

The first three cases were under the care of Dr. A. L. Jacobs and the fourth of Dr. M. G. C. Ashby, consultant physicians. We are grateful to them and to Dr. O. H. Belam, consultant anaesthetist, for their help and advice.

BARBITURATE POISONING

SIR,—From time to time the question of how best to treat acute barbiturate poisoning is raised. Nabarro¹ has emphasised the importance of restoring consciousness promptly by administering amphetamine, in order to prevent bronchopneumonia. Others believe that expert use of the bronchoscope and assisted respiration are sufficient until the effect of the drug wears off. In the following case the patient had taken an unknown amount of sodium amylobarbitone ('Sodium amytal') and phenobarbitone.

A depressive patient, aged 59, was seen at 8.45 A.M. by his doctor. He was unconscious with shallow respirations, small fixed pupils, and absent corneal, limb, and abdominal reflexes. He was given 6 mg. of picrotoxin and was then admitted to the Lymington and District Hospital under the care of Dr. R. J. McGill. In the next 3 hours he received a total of 60 mg. of picrotoxin, which resulted in generalised twitching and turning of the head, relieved by a small dose of thiopentone. Intravenous methylamphetamine was started, and at the end of 6½ hours he had been given 80 mg. The pupils

5. Foerster, S., Foerster, E., Maier, A., Blum, H. *Curr. Res. Anesth.* 1952, 9, 250.

became dilated and only the abdominal reflexes were absent. His blood-pressure was 136/80 mm. Hg and did not rise above 150/60 subsequently. He received 150 mg. of the drug in the next 4½ hours, after which he awoke and seemed to recognise his relatives. Dosage was continued with 330 mg. over another 4½ hours, at the end of which he was fully awake and able to eat without assistance. The total dose of methylamphetamine was 560 mg. over 15½ hours. For the next 24 hours he had decreasing visual hallucinations and was excitable though coöperative. Additional treatment during coma included oxygen by nasal catheter, rectal saline, and 1 million units of penicillin.

This patient was never on the verge of convulsions with methylamphetamine, as he was with picrotoxin; his blood-pressure remained normal. It seems safe to give large doses of methylamphetamine over a comparatively short time to patients in deep coma. Poe and Karp² describe a case in which a total of 520 mg. was given, but no times are stated.

Poole Hospital,
Nunthorpe, Middlesbrough.

C. F. HINGSTON.

DEMONSTRATIONS OF HYPNOTISM

SIR,—The Hypnotism Act of 1952 was initiated and passed to curb the dangerous and degrading spectacle of stage hypnosis and to stop the abuse of a recognised medical technique as entertainment for the public. Are we any further now that the Act is a fact? Today we read³ of a television demonstration of tooth-pulling by a dentist, using hypnosis. Yesterday we read⁴ of a layman who publicly demonstrated hypnosis on members of his audience and who was prosecuted under the Act and acquitted because he gave a "lecture" and no collection was made. We repeatedly read in the lay press articles by or about certain doctors and others practising hypnosis. This conduct should not be permitted and can only be controlled by a stronger Act or adequate action by a disciplinary body.

If hypnotherapy is to achieve its correct status and position in medicine, it must not be abused. We are not asked to witness the extraction of teeth under thio-pentone or nitrous oxide on television, for it would not be tolerated by medical authority. Could we not expect the same consideration for a valuable therapy even now in the experimental stage?

London, W.1.

GORDON AMBROSE.

EXERCISE TESTS DURING TREATMENT OF HYPERTENSION

SIR,—In your issue of Oct. 3, Dr. Vagn Rønnev-Jessen reported 2 cases of hypertension in which, after the administration of hexamethonium, a fall in blood-pressure set in after physical exertion. He postulated that the change of blood-pressure following exertion was a guide to the level to which blood-pressure should be reduced by treatment.

We should like to report the results of similar tests on the effect of exercise on systolic and diastolic blood-pressure in normal and hypertensive individuals before and after the administration of tetraethyl ammonium bromide (T.E.A.B.). Our results partly confirm those of Dr. Jessen.

88 tests were performed on 73 people; 35 had a normal blood-pressure, 28 had essential hypertension, and 10+ had renal hypertension. Blood-pressure and pulse-rate were taken in the lying position until the resting level was reached. The patient then performed 20 deep knee-bends in one minute; immediately afterwards, the blood-pressure and pulse-rate were again recorded every minute for a period of at least 10 minutes. After a prolonged rest, 0.3 g. of T.E.A.B. was injected intravenously, and the above exercise test was then repeated.

We found that the systolic pressure of hypertensive and normotensive individuals rose after exercise. But the diastolic

pressure reacted differently in hypertensive and normotensive persons: in the normotensive it almost invariably decreased in the minutes immediately after exercise (out of a total of 41 observations, only 4 showed an increase); in essential hypertension it usually rose (a decrease was noted in only 5 out of 36 observations). The difference between the reaction of the two groups was significant by the "t" test.

Exercise after T.E.A.B. generally increased the diastolic pressure of hypertensive patients in the same way as before, the increase in the mean value being rather greater; in normotensive patients, however, the previous decrease was no longer observed.

These findings are opposed to the conclusion of Stevenson et al.¹ that the blood-pressure of patients with essential hypertension reacts differently from that of normotensive people because of psychic factors and not as a result of exercise.

The cardiac output per minute in both hypertensive and normotensive patients is known to increase as a result of exercise, so the different behaviour of diastolic pressure in the two groups can only be attributed to the fact that exercise produces a greater fall in the peripheral resistance of normal individuals.

Although exercise affected the diastolic pressure less after the administration of a ganglion-blocking agent, in 2 cases exercise was followed by a substantial drop in blood-pressure and a state of semi-collapse, which confirms Dr. Jessen's observations.

THE AFRICAN MIND

SIR,—Your annotation of Jan. 30, under the title Comparative Psychiatry, discusses the psychiatric section of Dr. Carothers's monograph on *The African Mind in Health and Disease*. His observations are based on an earlier study,³ which was devoted to a careful analysis of the cases admitted over a period of 5 years to the African mental hospital in Kenya, and which raises, as you suggest, many interesting points of comparison between types of mental disease found in European and African communities.

This section involves, however, only one chapter in Dr. Carothers's monograph—a chapter which will probably only attract the interest of specialists in this field. A chapter which will, I imagine, arrest the attention of a wider group of readers is that on psychology, in which the author develops his views on the African mind in health. These are also based upon a previously published study,³ but one which unfortunately falls far short of the earlier one in standard of scientific inquiry. The evidence, in fact, which Dr. Carothers presents in support of his view that African behaviour resembles that of a leucotomised European psychopath consists of 33 personal and subjective anecdotes purporting to depict "unreliable behaviour in Africans." For example, one of these (and not the most surprising) reads as follows:

"I put my shoes to be mended in my shopping basket the night before so that I shall remember to take them to the cobbler the next day; the house-boy takes them out, cleans them, and puts them elsewhere, though he might assume that they had been put in the basket for some purpose."

Readers—and particularly those with some experience of East African mores—will be able to think of many explanations for this alleged shortcoming, but the point I wish to stress is that this is not the kind of evidence upon which serious conclusions can be based.

In short, the contrast between the methods by which Dr. Carothers has arrived at his psychiatric and at his

psychological conclusions is so great that I think it would be regrettable if readers were to be led by the evident erudition of his monograph, or by the *imprimatur* given to it by W.H.O., to regard both parts as of equal scientific validity.

Kampala, Uganda.

J. McFIE.

DIET AND CORONARY DISEASE

SIR,—Professor Duguid (May 1) distinguishes two forms of atherosclerosis but says: “in both processes the mechanism . . . is the same; solid matter is deposited on the intimal surface and in due course covered with endothelium and incorporated in the intima.” Why not accept this as the essential pathogenesis, and regard narrowing as something additional?

A study of the pathology of mental disease (where the cardiovascular system is oftener at fault than the central nervous system) gives support to the mural thrombi origin of atheroma as put forward by Professor Duguid. In addition I have illustrated streptococci¹ attached to vessel walls; and atheroma localised to an area contiguous to a sphenoidal empyema,² presumably where phagocytes and red-cell clumping had adhered.

It is often possible to see in histological sections that local vessel dilatation is the result of an atheromatous process, and I generally find that extreme atheroma has fixed the vessel in a state of dilatation.⁴ Where, however, thrombosis is complete as in Professor Duguid's figs. 1 and 2, narrowing might be expected, as also where the adventitia becomes involved. In one case the internal carotid artery was reduced to a fibrous cord.³ (This patient died from thrombosis of the superior mesenteric artery.)

The effects of occlusion of the small coronary vessels are not, as Professor Duguid states, negligible. Acute cardiac failure or local heart-wall rupture⁵ occurs when anastomatic vessels cannot relieve an additional small occlusion or spasm.

Atheromatous ulcers release lipid into the circulation,⁶ so a high blood-cholesterol level may be a sequel as well as a cause of atheroma.

Birmingham.

F. A. PICKWORTH.

SIR,—I cannot agree with Professor Duguid (June 5) that restricted fat consumption “could not have been the factor responsible for the discontinuity in the recorded death-rates beginning to appear as early as 1940.”

The following figures⁷ show the supplies of “fat from all sources moving into consumption in the United Kingdom” as a percentage of the pre-war (1934-38) consumption:

1940	1941	1942	1943	1944	1945	1946	
93	87	91	89	95	89		86
1947	1948	1949	1950	1951	1952		
82	85	93	101	97	94		

It will be seen that the most severe fat restriction occurred after the end of the war (not in the later war years as stated by Professor Duguid). My graph of coronary-disease death-rates (May 22) shows that the discontinuity first became evident in 1941 (not 1940), by which time the fat consumption had fallen to 87% of the pre-war level. Further it must be remembered that the fat-consumption figures are averages for the whole population and that the rationing of fats (which began early in 1940) would cut the consumption of those persons with the highest intake while those with the lowest consumption would be little affected. In my opinion all this fits in with the theory that restricted fat consumption could be the cause of the discontinuity in the recorded death-rates from coronary disease.

1. Pickworth, F. A. *Z. ges. Neurol. Psychiat.* 1932, 141, 420; fig. 3.
 2. Pickworth, F. A. *Chronic Nasal Sinusitis*. London, 1935; fig. 16.
 3. Pickworth, F. A. *Nursing Mirror*, Oct. 18, 1947, p. 45; fig. 2.
 4. Pickworth, F. A. *New Outlook on Mental Diseases*. Bristol, 1952; plate II, p.
 5. *Ibid.*, plate II, o and r.
 6. *Ibid.*, plate II, l.
 7. *Ministry of Food Bulletin*, Sept. 19, 1953.

A possible reply to my argument is, Why is the discontinuity in the death-rates more or less confined to the war years, although the fat consumption fell still lower after the war and rationing was continued until this year? My answer to this is that I do not think the discontinuity is confined to the war years, but that it has continued long after the end of the war. Consideration of the trend of the death-rates from coronary disease is complicated by the steep upward trend probably largely due to changing fashions of certification and similar causes. This makes it difficult to determine the true extent of the war-time discontinuity, while there is also the further difficulty that the national statistics of deaths from all forms of heart-disease are notoriously difficult to interpret owing to what has been referred to as “a good deal of switching of diagnostic labels.” Elsewhere⁸ I have tried to deal with some of these rather involved questions and have given a number of graphs of the death-rates from several different forms of heart-disease. Here I would say only that during the years 1931-49 the death-rates (by age-group) for degenerative heart-disease as a whole rose fairly steadily up to 1940, fell steeply until 1942 or 1943, and thereafter rose again, but at a slower rate than before 1940.

On the biological evidence for and against the fat theory, I am not competent to comment; but, if I understand it correctly, a possible interpretation is that a high consumption of fat may be a cause of coronary disease, and I feel that this interpretation is strengthened by the known trends of the death-rate and the consumption of fats since 1940.

Harrow, Middlesex.

R. H. DAW.

CLINICAL TESTS FOR KETONURIA

SIR,—Thank you for publishing the most enlightening paper by Dr. Nash and his colleagues (April 17). The nitroprusside-tablet test is of particular interest. I strongly deprecate the disgusting business of old-fashioned urine-testing, as still practised in such semi-public places as hospital clinics and doctors' consulting-rooms.⁹ It is very much to be hoped that tablet tests will soon become the generally accepted routine when testing urine for pH, reducing substances, ketone bodies, and bile pigments.

It is a pity that Dr. Nash and his colleagues do not tell us the exact composition of these nitroprusside tablets. It is also a pity that obscurity should have been allowed to creep into an otherwise remarkably lucid paper, over the chemistry underlying the tests described. It is not quite correct to state that some consider only acetone gives a purple coloration with nitroprusside, whereas others consider both acetone and aceto-acetic acid give it.

Actually, it is a very simple matter. Compounds with a ketonic grouping in a certain position give this reaction—e.g., acetone, which is dimethylketone (CH₃)₂C=O. Aceto-acetic acid, however, exists in solution as an equilibrium mixture of two slightly different forms, known respectively as keto and enol tautomers. The keto form has the following configuration:

With a shift in the position of the double bond, caused by the migration of one hydrogen atom, the enol form is produced which has the following configuration in which, for clarity, I have asterisked the hydrogen atom which has migrated:

The keto form has a structure closely akin to that of acetone. This form—and this form only—reacts, like

8. *J. Inst. Actu.* (in the press).
 9. Adams, A. V. *Med. World, Lond.* 1952, 76, 464.

acetone, with nitroprusside, as might be expected. However, by the law of mass action, in proportion as the keto form is used up in the reaction so will more be regenerated from the (non-reacting) enol form.

Likewise, the enol form has a hydroxyl group closely resembling that of such compounds as phenol and salicylic acid. It is the enol form—and this form only—that gives the Gerhardt reaction with ferric chloride, as do phenol and salicylic acid. It is precisely this that accounts for the interference with the Gerhardt test caused by the excretory derivatives of many commonly used drugs. Distinction from these is possible because aceto-acetic acid is readily hydrolysed on boiling, either to acetone and carbon dioxide or to acetic acid, according to the pH of the solution.

Heathfield, Sussex.

ADRIAN V. ADAMS.

SIR,—With reference to the article by Dr. Nash and his colleagues and subsequent letters (May 1 and 15), I should like to draw attention to a simple test for distinguishing between true and false positive Gerhardt reactions.¹

1. Drop of concentrated nitric acid is added to 1 inch (about 4 ml.) of urine in a test-tube, and the mixture is boiled for one minute. After cooling thoroughly, $\frac{1}{2}$ inch (about 2 ml.) 10% ferric-chloride solution is added.

Aceto-acetic acid is completely destroyed by this procedure, and the reaction will now be negative. Drugs will still give a positive reaction.

ACUTE APPENDICITIS IN LATE PREGNANCY

SIR,—In his interesting article last week Mr. Parker rightly stresses the difficulty of deciding whether the source of tenderness is uterine or extra-uterine. No single sign is likely to clinch the diagnosis in an abdominal emergency during pregnancy, but the sign described by me² may be found useful in this connection:

“With the patient lying straight on her back, the examining fingers find the area of maximum tenderness to pressure on the abdominal wall. While the fingers remain in contact with that area without altering the intensity of pressure they are exerting to elicit pain, the patient is made to turn over on to the opposite side so that the plane of the anterior abdominal wall is approximately vertical. The pain produced by the pressure of the fingers will be less or will have entirely disappeared if the lesion is uterine and has fallen away from the examining fingers—‘shifting tenderness’ (concealed accidental hæmorrhage, Case 3, or degenerated uterine fibromyoma, Case 4); pain sensation will be unaltered if the lesion is extra-uterine—‘fixed tenderness’ (due to appendicitis, Cases 1 and 2, renal or gall-bladder disease, ovarian cyst with twisted pedicle, diverticulitis).”

N. ALDERS.

B.C.G. VACCINATION

SIR,—After reading that in the U.S.S.R. children are vaccinated repeatedly from birth till leaving school,³ I would like to describe my experience of ordinary intradermal injections of 1 ml. and of multiple puncture by Professor Heaf's six needles.

By the end of 1952 I had done 2500 ordinary vaccinations with only 1 case of adenitis and half a dozen with ulcers 12–15 mm. in diameter. However, as even the mildest of vesicular reactions takes some considerable time to heal and in many cases ulcers 6–8 mm. in diameter last for months and may cause parents to withhold permission for vaccination, I thought I would try multiple puncture.

Early in 1953 I applied this method to 40 children—the technique was to put a drop of B.C.G. ordinary intradermal strength (0.25 mg. per ml.) on the arm and release the spring of the M.P. apparatus half a dozen times. On

subsequent test 35 gave a positive Mantoux reaction, although the local reaction on the deltoid area consisted simply of numerous tiny papules 1.5 mm. in diameter and height. The reaction was not so strongly positive as after intradermal injection. Hence doubt arose as to the value of this method and as to whether the conversion would persist for any length of time. Now after fifteen months all except 2 of the 22 children re-tested have given positive reactions varying from very slight to quite definite.

I had requested permission to use B.C.G. 20 mg. per ml., or dried B.C.G. which I could dilute to the required concentration; but the authorities would not countenance this experiment.

It seems to me that if this simple, safe, and rapid procedure can produce allergy lasting two years it will appeal to a much wider public and prove unobjectionable to parents.

Stornoway, Lewis.

R. STEVENSON DOIG.

AN AMERICAN IN BRITAIN

SIR,—I was greatly discouraged and depressed that a journal with the standing of *The Lancet* would publish such a statement as that of Dr. Cort in the June 19 issue. Perhaps it is because of your unfamiliarity with American military draft procedure. It would also appear that the University of Birmingham has been misled. This type of reporting is more characteristic of the lay press.

In America medical students are “deferred” from military service during their undergraduate study and for one year afterward while in the internship or other advanced study. Please note that they are deferred and not “exempt.” At the end of this time they are, if physically, mentally, and morally fit, commissioned in the appropriate service for a period of 21–24 months. Loyal citizens do not attempt to evade this obligation. While discharging this obligation several of Dr. Cort's classmates have become casualties in such places as Korea in an attempt to keep the world free so that research may continue.

Dr. Cort's statement is a cleverly worded piece of evasion and diversion which may mislead the British doctor, but it will certainly not confuse any American physician. The issue at hand is not Communism as he would like for you to believe; but instead, it is evasion of military service, or to use the American vernacular simply “draft dodging.” Without attempting to analyse all of his statements I shall comment on only a few.

He mentions several colleagues who were dismissed from their jobs because of Communism. This is untrue. These men were in junior positions and when the terms of their appointments expired they went into the private practice of medicine. He recalls one who remained as being defendant in a suit brought by the State of Massachusetts for “violation of his oath.” The fact that one of his colleagues did remain attests to the fact that Communism was not an issue.

He also mentions that upon his return to America he will be subject to unemployment. This is not true. He is eligible to obtain a licence and enter into the practice of medicine in any of the 48 States, territories, or possessions. If, of course, he expects to obtain a professorship, he may well be unemployed.

As to the loss of citizenship, it is impossible to deprive a natural-born citizen of his citizenship. A naturalised citizen may be repatriated if his citizenship was obtained on the basis of fraud.

As to the 5–10 year prison sentence he mentions, this can be given only upon conviction of a felony. If a felony is involved, he will have ample opportunity to defend himself before an impartial jury of twelve. If the decision is adverse, he may proceed to a court of appeals and in an exceptional circumstance he may even advance to the United States Supreme Court. To put the matter more simply, an honest citizen has nothing to fear.

The proper thing for Dr. Cort to do is to stand up straight on his hind legs like a man and volunteer for his

military service without hiding behind such statements as "not legally binding," the tolerance of the British Government, and any emotion he may elicit from the ill- or mis-informed public. If at the end of his service he so desired he could return to England as an immigrant if the country would still accept him.

As to his immediate future I am sure that between the American embassy and the Home Office justice will be obtained. The press would do well to stick to the official announcements of these bodies.

AN AMERICAN DOCTOR IN ENGLAND.

ROSE SIMMONDS MEMORIAL FUND

SIR,—In December, 1952, you published an appeal for contributions to the above fund.¹ The object was to provide an educational fund which, through the British Dietetic Association, would offer scholarships to students to train as dietitians, or prizes to students in training.

A sum of £370 has now been contributed. This money has been invested, and the trustees have decided that prizes shall first be available in the autumn of 1955.

Medicine and the Law

Death after Tonsillectomy

AT an inquest on a 7-year-old girl at Barnet on June 14 the coroner criticised the emergency arrangements at a local hospital.²

The child's tonsils were removed on May 26 at St. Stephen's Hospital; there were no complications at operation but some four or five hours later, at 8.45 p.m., hæmorrhage was noticed. The surgeon, who was at Barnet General Hospital, was kept informed; he ordered an injection which was given at 9.15 p.m., and after a further message went to see the child at 10 p.m., when he ordered her removal by ambulance to Barnet General Hospital. There he operated to stop the hæmorrhage and gave blood-transfusions, but the child died.

The bleeding was noticed at a time when day staff was handing over to night staff, and the surgeon was not available on the premises. As there were no facilities at St. Stephen's for the operation and blood-transfusion, the child had to be removed by ambulance, all of which caused delay.

Recording a verdict of death by misadventure the coroner said that the arrangements were perhaps inadequate for an emergency of this sort and he would bring the matter to the attention of the authorities responsible.

Public Health

First Quarter in Scotland

IN the quarter ended March 31 this year³ the birth-rate in Scotland was 18.6 per 1000 population, which was 0.5 above the rate for the corresponding quarter of 1953 and 0.1 above the average in the previous five years. Stillbirths amounted to 25 per 1000 total births. The death-rate was 14.3 per 1000 population—0.6 more than in the corresponding quarter of 1953 but 0.8 below the five-year average. The infant-mortality rate was 38 per 1000 live births, and the neonatal-death rate 24 per 1000 live births. Deaths from tuberculosis amounted to 31 (respiratory 28) per 100,000 population, compared with 32 (27) in the first quarter of 1953 and a five-year average of 56 (49).

Obituary

CHARLES COLGATE HOLMAN

M.A., M.B. Camb., F.R.C.S.

Mr. C. C. Holman, emeritus surgeon to Northampton General Hospital, died on June 17 at the age of 69.

He was born at East Hoathly, where his father and his grandfather were both in general practice. From Eastbourne College he went to Caius College, Cambridge, where he took the natural sciences trips in 1905. Following a family tradition he finished his medical education at Guy's, qualifying in 1908 and graduating M.B. in 1909. After serving as house-surgeon at Guy's he held other resident appointments at Addenbrooke's Hospital, Cambridge, at the Norfolk and Norwich Hospital, and at Brighton and Hove Hospital for Women. In 1912 he took his F.R.C.S., and the same year he began his long association with Northampton when he received a house-appointment at the General Hospital. Soon afterwards war broke out and he joined the R.A.M.C., serving for a year in Mesopotamia.

On his return to Northampton he became assistant surgeon to the General Hospital in 1919, and he later joined the staffs of the Manfield Orthopædic Hospital and the Kettering and District General Hospital. When he retired from the staff of the Northampton General Hospital in 1952 he was appointed emeritus surgeon. During his too short retirement he continued his habit of contributing cogent and incisive letters to our columns, and earlier this year he began his last article with the characteristic words: "After forty years' work I am still seeking the answer to the following questions about cancer of the breast. . ."

R. O. L. writes: "Charles Holman was a modest man who shunned publicity except when he had something of real importance to say. For this reason his merit as a surgeon may not have received full recognition outside his own area, and only those who worked beside him came to know and appreciate his true worth. Thirty-three years of consulting work gave him a vast experience which encompassed the whole range of general surgery and at one time included gynæcology and orthopædics. In 1939 he formed the first fracture unit at Northampton General Hospital, and from then until 1946, in addition to his general work and with the aid of one houseman, he dealt with all fractures coming to the hospital. His capacity for work was enormous: holidays meant time lost from work and it was an exception for him to be away more than ten days in any year. In operating he was sound and generally conservative; in judgment sure, and in criticism generous.

"A quiet thoughtful man, he kept meticulous records; he also read widely in the medical journals, and his contributions to them were always well balanced and valuable since they were based on his own wide experience. His recreations were simple; lawn-tennis at which, despite a disability resulting from poliomyelitis in childhood, he was an enthusiastic performer and a difficult man to beat, and bridge which he enjoyed and took not too seriously.

"His name was a household word in Northamptonshire and North Bucks and he is mourned by all who knew him."

Mr. Holman is survived by his second wife, Miss V. Lewis, whom he married in 1924. Of the two sons of his first marriage to Miss V. E. Foxell, who died in 1921, one is a doctor.

EDWARD JAMES BOOME

T.D., M.B. Birm., M.R.C.P.

Dr. E. J. Boome, consultant in speech therapy to the London County Council, died on June 12 while on holiday in Devon.

He graduated M.B. from the University of Birmingham in 1907. After holding house-appointments in Birmingham at the General Hospital and the Queen's Hospital, he took the D.P.H. in 1912, and the following year he joined the public-health service of the London County Council. During the 1914-18 war he served in France as a Territorial medical officer, reaching the rank of major and being mentioned in despatches. On demobilisation he

returned to his post with the L.C.C. as assistant school medical officer and his work ranged widely over school medicine. He was an authority on the ascertainment of defective children. For a time he was visiting medical officer to the Farmfield Institution for Mental Defectives and lecturer to the nursing staff. In 1934 he was promoted to be a principal assistant medical officer. A pioneer in the study of speech defects, he was a founder fellow of the College of Speech Therapists. He was responsible for the development of speech therapy in the council's service and he became its consultant on the subject. He was the joint author of several textbooks on the nature and treatment of speech defects, including *Relaxation in Everyday Life* (1938) and *Abnormal Speech* (1930). For several years he also shared in the examination of the council staff, bringing to the work clinical skill and charm. His commanding presence, wit, and courtesy will make him difficult to replace.

Mrs. Boome survives him.

Dr. A. L. P. PEENEY

A. V. N. writes: "His fellow consultants will note the great gap caused by Peeney's absence from that mecca for friendly and constructive clinical chat—the warm and welcoming clinical pathology laboratory in the Queen Elizabeth Hospital at Edgbaston. His persistent ability to gather his clinical colleagues together for discussion on research work, and his inclination to leave himself somewhat in the background, were characteristic of the quiet unobtrusiveness of his daily life and work. Many resident officers and medical students have reason to be grateful for the trouble and care he gave to their laboratory work and instruction. Those of us who knew him more intimately came to understand a sound philosophic mind and a man who never withheld kindness and sincere help."

Dr. A. J. M. BUTTER.—Our obituary notice (June 12) contained a personal tribute from J. A. B. Y. This was a shorter and altered version of what was sent to us; and, as the writer informs us that he would not have wished it to appear in that form, we must express our regret that he had no opportunity to correct a proof before publication.

Appointments

BILLINGHURST, MARGARET A., M.B. Lond., D.O.M.S.: refractionist (S.H.M.O.), Westminster Hospital, London, S.W.1.
 DREW, D. W. A., M.R.C.S.: anaesthetic registrar, South Devon and East Cornwall Hospital, Plymouth.
 EDGAR, WILLIAM, M.B. Edin., D.P.H., D.O.H.: deputy M.O.H., and deputy school M.O., Luton.
 GLOVER, J. R., M.B. Camb.: M.O., Westinghouse Brake and Signal Company, Ltd., Chippenham, Wilts.
 KENNEDY, C. C., M.D.: consultant clinical pathologist, Belfast City Hospital.
 McGRATH, S. D., M.R.C.P.I., D.P.M.: physician in charge of clinical research, St. Patrick's Hospital, Dublin.
 PRESTON, A. E., B.M. Oxfd.: deputy director, blood-transfusion service, Oxford.
 WINN, J. M., B.A. Camb., M.R.C.P., D.M.R.D.: consultant radiologist, Leeds General Infirmary.

Leeds Regional Hospital Board:

COXON, J. G., M.B. Lond., F.R.C.S.: part-time consultant in general surgery, Dewsbury and Halifax areas.
 DONOVAN, J. F., M.R.C.S., D.P.M.: consultant psychiatrist and physician-superintendent, Broadgate Hospital, Beverley.
 NEWCOMBE, JOHN, M.B., D.P.M.: consultant in psychiatry, mental deficiency hospitals and hostels, Hull and East Riding areas.
 SMART, G. A., M.B. Glasg.: asst. chest physician (S.H.M.O.), chest clinics, hospitals, and sanatoria, Hull area.
 WELMINSKY, ANTONIN, M.D. Prague: asst. chest physician (S.H.M.O.), chest clinics, Pontefract, Goole, and Selby areas.

Liverpool Regional Hospital Board:

EDWARDS, K. C. S., M.R.C.S., D.P.M.: whole-time consultant psychiatrist, Deva Hospital.
 GORE, C. P., M.D. Dubl., M.R.C.P.I., D.P.M.: whole-time consultant psychiatrist, Rainhill Hospital.
 MARKS, K. L., M.B. Edin., M.Ch.(ORTH.) Lpool, F.R.C.S.E.: consultant orthopedic surgeon, Chester and central Wirral areas.
 STEAD, A. L., M.D. St. And., F.F.A. R.C.S.: part-time consultant anaesthetist, Liverpool city area.
 WALKER, ERIC, M.D. Lpool, D.P.H., D.M.R.D.: part-time consultant radiologist, East Liverpool area.

The Hospital for Sick Children, Great Ormond Street, London:

CARTER, C. O., B.M. Oxfd., M.R.C.P.: part-time medical geneticist (S.H.M.O.).
 CLARK, WENDY A., M.B. Lond., F.F.A. R.C.S.: junior resident anaesthetist.
 O'MEARA, P. A., M.B. N.U.I., D.L.O.: registrar, E.N.T. department.
 SLOMAN, LIZBETH, M.D.: house-physician to Professor Moncrieff.

Notes and News

OUTPATIENT DEPARTMENTS

At a conference held by the Association of Hospital Management Committees in Scarborough on June 17-19, the Marquess of Normanby (chairman of the board of governors of King's College Hospital) said that, except for casualties, the outpatient department should be reserved for consultative and treatment clinics, to which patients must be referred by the general practitioner: "we should at all costs try to prevent the hospital entering into direct relationship with a member of the public, without going through the general practitioner." Meetings between hospital consultants and general practitioners helped to abate the pressure on this department. Consultants, for their part, might "weigh up in their hearts the value of their membership on each committee as set against the value of their regular and punctual attendance at outpatients." Those in charge of outpatient clinics should give priority to this work over any other, except emergency calls in the wards. As regards the structure of the department, "I am personally not at all impressed by palatial surroundings, but I am deeply impressed if there is someone at hand to discuss any problem arising or to explain to the patient the cause for delay or the cause for any other thing that has gone wrong." Outpatient departments contained much expensive equipment, which should be fully used. It was surely not impossible to envisage a modification of the idea of health centres based on the use of hospital outpatient departments in hours when the hospital doctors were not in attendance.

Mr. G. L. Thompson, as a consultant, spoke of the need for "simple" prescribing not only for inpatients but also for outpatients. Mr. S. Clayton Eryers (formerly chief administrative officer, Leeds United Hospitals) said that nine out of ten complaints came from dissatisfied outpatients. He did not know whether it had been established that the patient had a right to see a consultant: a large number were seen by more junior doctors. Beds might be saved if outpatients were examined thoroughly by consultants; commonly more junior members of the staff felt that they should admit patients, and it might thus be economic to have more consultants.

OUTPATIENT WAITING: THE OTHER SIDE

PATIENTS who do not keep their appointments were the subject of strong comment at a meeting of the Bournemouth and East Dorset Hospital Management Committee reported in the *Bournemouth Times* of June 4. Further facts were given by Mr. E. J. Whitney, secretary of Poole Hospital, in an interview with the *Poole Herald* (June 9). This hospital's house-committee, he said, had long been much concerned to reduce the time that outpatients waste, and by last October had managed to cut the average waiting-time to half an hour. But consultants complained that patients often ignored their appointments, and a check made over a period of five weeks showed that this was done by 88 new patients and 292 old patients—i.e., some 10% of all the patients treated during the period. "Not one of them gave us any warning, or contacted us in any way, in spite of the fact that the appointment card specifically asks them to notify us immediately if for any reason they are unable to attend." The time wasted in this way could have been used to reduce the delay of several weeks before new patients can be seen in some of the departments. Mr. H. R. Rees, deputy group secretary, stated that little could be done except to advise the doctor who fixed the appointment. "Then it is up to him to ask the patients why they did not turn up."

SICK-LEAVE FOR HOSPITAL STAFFS

Mr. G. A. Paines, secretary of the Croydon Hospital Management Committee, comments in the *Municipal Journal* (May 21) on "the apparent decline" in the health of some hospital employees of all grades since the inception of the National Health Service in 1948. "Matrons and hospital secretaries," he declares, "have often been worried, and at times distraught, particularly on the days following public holidays or weekends, by the increased incidence of periodical sickness, which has multiplied each year since 1949." In one group of hospitals, employing under 2000 people, the position became so serious that in 1952 the management committee decided on a special investigation.

An establishment subcommittee, comprising a doctor, a nurse, and a trade-unionist, all members of the management committee

looks into the periodical absences of all grades of staff and then recommends: (a) that the case be reviewed again in three, six, or twelve months; or (b) that the employee be sent for medical examination, after which his own doctor has the right to submit an opinion to the medical referee; or (c) where the medical referee has previously advised that ill health makes a person unsuitable for employment in his present job, and there is no alternative employment available, that reasonable notice be given to terminate employment.

The matter is then considered by the establishment committee, of which the chairman is a doctor not employed in the National Health Service. The investigating group, after further consideration, makes a recommendation to the management committee. A special committee to hear appeals, consisting of three members of the management committee who ordinarily have nothing to do with staff matters in the group, has been set up.

Since this procedure has been in operation 45 employees have had their services terminated. The management committee decided to send for medical examination those members of the staff nominated by the establishment subcommittee.

In the first ten months of the new arrangement the total amount of periodical sick-leave lasting three days or less (without medical certificate) fell by 65%, and sick-leave of over three days (with medical certificate) by 22%.

The inquiry revealed that in 1951 all sickness had increased from the 1947-48 levels as follows: nursing 60%; ancillary staff 25%; other staff 300%. Absences of one, two, or three days without medical certificate had increased by 200%. In 1953 non-resident staff averaged 33% more total sickness than resident; while full-time non-resident staff had a higher proportion of sick-leave than part-timers. Full-time non-resident nurses had 50% more sick-leave than residents; similarly sick-leave among non-resident ancillary staff was 250% greater, and among part-time ancillary staff 300% greater.

Mr. Paines concludes that other employing authorities may wish to collect similar statistical information. "The comparisons may surprise."

A REGISTER OF BENEFITS

THE Ministry of Pensions and National Insurance have revised their helpful booklet, *How, When, and Where to Claim Benefit*, which gives a clear summary of the different benefits to which the sick, injured, unemployed, pregnant, or ageing citizen is entitled. As its title promises it gives succinct instructions as to how and where he (or she) should set about making his claim, and it ends with a list of the standard weekly rates offered in each category. Free copies of the booklet may be had from the information division of the Ministry, 10, John Adam Street, London, W.C.2.

FOUNDRY-WORKERS

THE general secretary of the Amalgamated Union of Foundry Workers has issued for his members a booklet¹ which tells them what is being done for their health, safety, and welfare. It is divided into five parts, with a preamble which gives a somewhat unbalanced account of the formation of the two committees which have dealt with conditions in steel and iron foundries respectively.

Part 1 contains in full the recommendations of the Joint Advisory Committee on Conditions in Iron Foundries,² but not those of the senior committee on dust in steel foundries which is only mentioned in passing. The new Iron and Steel Foundries Regulations, 1953, are given in full with notes on each regulation. Regulation 7, which deals with the suppression of dust in fumes, is said to be the "most comprehensive in its general effect, dealing as it does with the greatest hazard in the industry." Subsection 6 of regulation 7 says that "all dressing or fettling operations shall be carried out in a separate part of the foundry suitably partitioned off; or in an area of the foundry set apart for the purpose; and shall, so far as reasonably practicable, be carried out with effective and suitable local exhaust ventilation or other equally effective means of suppressing dust, operating as near as possible to the point of origin of the dust." The regulation does not come into operation until Jan. 1, 1956—i.e., twelve years after the setting up of the Dust in Steel Foundries Committee, which was appointed primarily to deal with the problem of dust in the fettling of steel castings. Descriptions and illustrations are given of a new fettling bench to which exhaust ventilation is applied; of an improved exhausted grinding machine; of a swing frame grinder fitted with exhaust ventilation; and also of a new hollow exhausted

pneumatic chisel. We hope that these and other improved machines will speedily be installed in all foundries even before 1956, because the medical branch of the Factory Department has been drawing attention, since before the 1939-45 war, to the serious risk of silicosis in steel fettlers. The risk to health was again emphasised in 1950 in the comprehensive report by A. I. G. McLaughlin and his co-workers.³

In the preamble to the booklet it is stated that a new joint standing committee on non-ferrous foundries has now been appointed. It is added that there is ample scope for intensive investigation into conditions in this group of foundries and that a review of the Brass Casting Regulations, 1908, is overdue. Part 3 contains in full 15 different codes of regulations which apply in varying degree to foundries, and in particular the Blasting (Castings and other Articles) Regulations, 1949, under which the use of sand as an abrasive is prohibited; and the Foundries (Parting Materials) Special Regulations which prohibit the use of silica parting powders. Both these codes of regulations were issued as a result of the recommendations of the joint standing committees and constitute real advances in preventive medicine.

In Part 4 extracts are quoted from the Factories Act, 1937, which are relevant to foundries. One important section (119) imposes duties on the workers to use (and not misuse) any appliance which is installed in a factory to secure their health or safety. The general secretary exhorts his members to play their part in using properly the facilities and equipment which the employers are legally obliged to supply. "By mutual appreciation of the benefits to be obtained by the improvements introduced, the foundry can be made a much healthier place than ever before."

Part 5 gives in full the National Insurance (Industrial Injuries) (Prescribed Diseases) Amendment Regulations, 1954; a list of the prescribed diseases; and (rather out of context) a description of some practical measures for reducing the amount of fume from oil-bonded cores.

Altogether, this is a useful compendium of information about the legal and practical aspects of foundry work.

TEETHING-POWDERS

IN a memorandum to lay journals the Ministry of Health makes the following observations on "so-called teething-powders":

Babies seldom, if ever, really need powders.

Most powders contain drugs which are harmless in an occasional dose, but which may be harmful if used repeatedly.

No mother should undertake the responsibility of repeated medication of a baby or young child without medical advice.

Babies and young children should never be given a routine "weekly aperient" whether as a "powder" or in any other form.

If a mother thinks her baby needs "powders" it is probable that there is something amiss in the feeding or management. Dosing with "powders" may only lay up trouble for the future, and she should talk things over with her family doctor or the doctor at the clinic, or ask the health visitor to come to see her.

HEALTH STATISTICS

THE first International Conference of National Committees on Vital and Health Statistics, held in London last October,⁴ was attended by delegates from twenty-eight countries (members or associate members of the World Health Organisation). The report of the conference, now issued,⁵ deals with the health and vital statistics required by the various countries and methods of improving their quality, and with the implementation of international regulations or recommendations of previous W.H.O. committees.

LONDON MEDICAL ORCHESTRA

ABOUT six months ago, a group of doctors, dentists, and nurses formed this orchestra. They gave their first concert in April, and on June 18 some of their members entertained the London Association of the Medical Women's Federation and their friends to an evening's music-making at the Royal Free Hospital School of Medicine. Works by Bach, Purcell, and Mozart were performed with a skill and understanding remarkable for an amateur ensemble. The large audience showed a particular liking for the performance of Bach's Brandenburg Concerto No. 5, in which a young medical student achieved a near-professional standard in playing the difficult part for the solo pianoforte.

RADIO IN CARS

THE Mobile Radio Users Association is seeking to ensure that the frequencies allotted to doctors with two-way radio in their cars shall not be interrupted by other users in the band. Those interested are invited to join the association and use its technical and legal services; the minimum annual subscription is one guinea, which includes a monthly newsletter. Further particulars may be had from Mr. Ronald Simms, secretary of the association, Buckingham Court, Buckingham Gate, London, S.W.1.

THE DORSET COASTLINE

THE lovely stretch of coast between Weymouth and Lyme Regis, with its wealth of tradition and local lore, and its old seaports, churches, and monuments, is handsomely celebrated, with the aid of many fine photographs, by a Dorset ex-Naval Surgeon.¹ Yachtsmen will enjoy the sailing yarns, and lovers of the English countryside and of wild birds will find much to delight them.

University of Oxford

Mr. P. R. Allison, thoracic surgeon to the Leeds United Hospital and the Leeds Regional Hospital Board, has been elected Nuffield professor of surgery from Oct. 1. Since the death of Sir Hugh Cairns in 1952 the chair has been vacant.

In 1927 Mr. Allison took his B.Sc. at the University of Leeds with first-class honours in physiology, and four years later he graduated M.B., again with first-class honours. After holding resident appointments at the Leeds General Infirmary he took his F.R.C.S. in 1932, and the following year he was appointed surgical tutor and registrar at Leeds University and in 1936 clinical lecturer in surgery. The same year he proceeded to the degree of Ch.M. and joined the honorary staff of the infirmary as assistant surgeon. In 1941 his specialist interest in chest surgery was recognised by his appointment as thoracic surgeon to the infirmary and clinical lecturer in thoracic surgery in the university, and he is at present in charge of the thoracic surgical department at the infirmary and regional consultant in his specialty. His numerous publications include papers on the reconstruction of the oesophagus and on the surgical treatment of carcinoma of the lung.

University of Sheffield

The Nuffield Foundation is to establish a research fellowship at the Sheffield centre for the investigation and treatment of rheumatic diseases.

University of Birmingham

Dr. Brian MacMahon has been appointed lecturer in social medicine. The following have been appointed part-time lecturers in obstetrics and gynaecology: Mr. A. L. Deacon, Mr. W. G. Mills, and Miss Dorothy Shotton.

University of Leeds

The council have instituted a new part-time chair of psychiatry and appointed to it Prof. D. R. MacCalman, formerly professor of psychiatry and head of the department of psychiatry.

This change has been made in deference to medical advice given to Professor MacCalman; it will enable him to devote himself to those sections of psychiatry in which he is especially interested, while relieving him of a substantial burden of administrative responsibility. It is expected that in due course a successor to him in the whole-time chair and the headship of the department will be appointed. Meanwhile, Dr. Mary Burbury, senior lecturer in child psychiatry in the university, will act as head of the department.

Royal College of Obstetricians and Gynaecologists

Two public lectures will be given in connection with silver jubilee celebrations which are being held at the college on July 13, 14, 15. On Wednesday, the 14th, Sir William Fletcher Shaw will deliver the William Meredith Fletcher Shaw lecture on The College—its Past, Present, and Future. On Thursday the 15th, Prof. Bruce T. Mayes, of Sydney, who is visiting this country as the Sims-Black professor, will deliver the William Blair-Bell lecture on the Making of an Obstetrician. Both lectures will be given at 11.30 A.M. at 1, Wimpole Street, London, W.1.

International Children's Centre

Some fellowships will be available for those who wish to work at the laboratories of the centre in Paris during 1954-55.

At present the programme of research of the centre is mainly devoted to anti-tuberculosis vaccination and anti-pertussis immunisation. Further particulars may be had from Professor Bugnard, International Children's Centre, Château de Longchamp, Paris 16.

1. The Dorset Coastline. By LEWELLYN PRIDHAM, M.R.C.S. B.N. ret'd. Photography by Edward Kestin. Dorchester: Longmans (Dorchester) Ltd. 1954. Pp. 126. 25s.

Ophthalmological Society of the United Kingdom

Dr. Robert Leishman (Glasgow) has been awarded the 1954 Treacher Collins prize for his essay on the Eye in General Vascular Disease: Hypertension and Arteriosclerosis.

Royal Medico-Psychological Association

The following have been successful in the association's examinations for the diploma in psychological medicine:

J. K. Arkle, U. B. H. Baruch, N. C. Connell, T. B. Stephens, R. M. Taylor.

British Diabetic Association

The annual scientific meeting of this association is to be held at University College Hospital Medical School, London, W.C.1, on July 16 and 17. On Friday, the 16th, at 2.30 P.M., Dr. K. Hallas-Møller (Copenhagen) will deliver the Banting lecture, on the Chemical and Physiological Background of the new Insulin Zinc Suspensions. The programme will also include discussions on the insulin zinc suspensions (opener, Dr. W. G. Oakley), and plasma-insulin estimations (Dr. P. J. Randle and Dr. J. Vallance-Owen). Further particulars can be had from the secretary of the association, 152, Harley Street, London, W.1.

Service Conference

A joint Services medical-surgical diagnostic and therapeutic conference is to be held at the U.S. Embassy, 5, Grosvenor Square, London, W.1, on July 22, 23, and 24. Speakers will include officers from the U.S. Air Force, the Royal Air Force, the Royal Army Medical Corps, the Royal Naval Medical Service, and the United States Navy, and British civilian physicians and surgeons. The conference is open to Service and civilian doctors. Further information may be had from Colonel L. Render Braswell, Headquarters Third Air Force, Office of the Surgeon, Victoria Park Estates, South Ruislip, Middlesex.

Medical Honours

Captain D. R. Boyns, R.A.M.C., has been appointed M.B.E. in recognition of distinguished services in Malaya.

In announcing the award *The Times* (June 19) relates that Captain Boyns fractured his back in a parachute descent in the Malayan jungle. But from the moment he landed he immediately started to help others who had been injured, moving from place to place over rough country. No-one knew that he had himself been hurt until after the operation was over.

Captain Alasdair Fraser-Darling, R.A.M.C., has been appointed M.B.E. in recognition of brave conduct in Libya on Jan. 15-16.

CORRIGENDUM: *The Disabled*.—The M.R.C. memorandum by Prof. T. Ferguson mentioned in our leading article (June 5) is no. 28.

LIVER INJECTION U.S.P. - 20 MICROGRAMS

**NOW AVAILABLE IN
GREAT BRITAIN**

LEDERLE'S undisputed reputation for superior Liver Extracts stems from a quarter of a century's experience in liver-extract research. Their latest liver extract—Liver Injection U.S.P.—20 Micrograms—described in a recent British study as "significantly more potent" than other extracts* is now available to doctors in Great Britain. Liver Injection U.S.P.—20 Micrograms *Lederle* contains 20 μ g. of vitamin B₁₂ activity in each cc. and is especially suited to the prolonged treatment of pernicious anaemia because of its small volume, high concentration of anti-anaemic substance and low concentration of solids—qualities which ensure minimum patient discomfort and maximum therapeutic effect. In addition it is outstandingly useful in everyday practice for hepatic and metabolic stimulation.

*A review of pernicious anaemia patients on liver extract maintenance over several years showed a deterioration in their red-cell count and clinical conditions. A change to Solution Liver Extract Concentrated *Lederle* (now known as Liver Injection U.S.P.—20 Micrograms) brought about striking improvement in 20 of the 25 patients who had been maintained on extracts, as well as in 3 patients who had neglected their treatments. The author concluded from the definite response to the change of treatment that the *Lederle* Extract was significantly more potent than those previously used.

8 to 24 hours of Allergy Relief

from a single dose of

DI-PARALENE

REGD.

(Chlorcyclizine Hydrochloride, Abbott)

ALLERGY patients like the convenience, effectiveness and economy of this longer-lasting antihistaminic. Published reports show that DI-PARALENE—with a piperazine side chain rather than one of the conventional type—in many cases provides 24 hours of relief with a *single* dose. Initially, DI-PARALENE should be administered in 50 mg. doses three times a day for the average adult, but in the majority of cases this can later be reduced to one or two doses a day. Side-effects are comparatively few and mild.

This season try longer-acting DI-PARALENE—
available in 50 mg. tablets, bottles of 25, 100 and 500.

Abbott

and other fungal dermatoses

The combined use of Mycil Ointment and Powder has proved to be highly effective in both prophylaxis and treatment of fungal dermatoses.

Mycil Ointment is formulated to ensure penetration of the active constituent, chlorphenesin, to the site of the infection.

Mycil Powder, used alone, prevents reinfection. Because of its absorptive properties it is a valuable agent with which to combat excessive perspiration.

Both preparations are non-mercurial and odourless and may be used over long periods, if necessary, without adverse effects.

PNEUMOCONIOSIS ABSTRACTS

Volume II—1939-1950

Reprinted from the *Bulletin of Hygiene*
by permission of the Honorary Managing
Committee of the Bureau of Hygiene
and Tropical Diseases.

This second volume, together with Volume I, contains all the abstracts of papers relating to pneumoconiosis which have been published in the *Bulletin of Hygiene* from the time of its first appearance in 1926 to the end of 1950. Volume II covers the period 1939 to 1950. The book is fully indexed and provides invaluable material for all research workers, medical students, and others studying pneumoconiosis.

Press Opinions of Volume I

'No medical man, however specialised, could fail to find something to interest him in this book; and many, because of their specialisation perhaps, will want to read it from cover to cover.'—*The Lancet*

'... most doctors who have preserved the habit of reading would enjoy each and any of the eighteen lectures printed in this volume.'

—*The British Medical Journal*

'If this volume gives any indication of what is to come in future volumes, the series will be extremely useful to all medical men...'

—*Medical Journal of Australia*

ISOTOPIC TRACERS

*A Theoretical and Practical Manual
for Biological Students and Research Workers*

G. E. Francis, W. Mulligan and A. Wormald

Professor Wormald and his colleagues were amongst the first in this country to use isotopic tracers in biological research, and for several years past have conducted in the Biochemistry Department at St. Bartholomew's Hospital Medical College a course designed to provide a fundamental knowledge of isotopic techniques. Their book has been developed directly from this course, and, in view of the small number of training centres where instruction in Isotope Methodology may at present be obtained, its emphasis on practical aspects should make it especially useful.

SENATE HOUSE, W.C.1

NEW BOOKS THIS MONTH**THE MEDICAL ANNUAL 1954**

Edited by **SIR HENRY TIDY, K.B.E.,**
and **R. MILNES WALKER**

With the collaboration of 43 contributors

72nd issue. $5\frac{1}{2} \times 8\frac{1}{2}$ ins. 522 pp. 67 plates and
32 text illustrations. 32s. 6d., post 1s. 3d.

This annual volume has for many years provided practitioners with a comprehensive review of the most recent developments and progress in every field of medical and surgical practice and has become world-famous as a standard medical reference.

"The literature already unmanageable enough for most readers, gets more and more out of hand, and the *Annual* has for many years been an excellent means of keeping it under control."

—*The Lancet.*

A SYNOPSIS OF OBSTETRICS AND GYNÆCOLOGY

By **ALECK W. BOURNE**

11th Edition. $4\frac{1}{2} \times 7\frac{1}{2}$ ins. 548 pp. 170 illustrations.
25s., post 7d.

This work sets forth orthodox views in a concise form suitable for rapid reference or revision. As with the other Synopses, it makes no claim to be a text-book, but a valuable supplement to text-books and an aid to the memory.

"Being full of meat, it will appeal not only to final-year students but to qualified men who want a quick handy reference or to registrars who have to teach students . . . a work that has long inspired affection and respect."—*The Lancet.*

JOHN WRIGHT & SONS LTD., BRISTOL, 8

In many restricted diets there is a tendency for certain essential nutrients to be deficient. Such shortages may arise with patients who are on special diets, for example, in cases of obesity, gastric troubles or diabetes, and also with old people living alone.

RESTRICTED DIETS

Among the essential nutrients which may be deficient in these circumstances are the vitamins of the B complex. In order to increase the vitamin B complex content of the diet and thus counteract this type of deficiency, Marmite is often recommended. Marmite is a concentrated yeast extract, which provides riboflavin and nicotinic acid, and also folic acid, pantothenic acid, pyridoxin, biotin, choline, inositol and *p*-aminobenzoic acid.

SERVICE TO THE LIMBLESS

DESIGN

in step with modern techniques

Craftmanship, personal service, quality. These are the foundations of HANGER "Service to the Limbless." Over the last forty years HANGER has been marching in the forefront of development in artificial legs, and has been responsible for most of the outstanding advances in design which have taken place during that period.

Hanger Hip lock for artificial limbs for amputation of the leg at the hip.

Double Swivel Pelvic Band with spherical attachment.

The wealth of experience which has been gained in fitting over 100,000 limbless is incorporated in every HANGER leg and ensures that the limbless person is being supplied with the finest prosthesis which modern science can make available. It is an undisputed fact that more HANGER legs are prescribed than those of any other maker, sure proof of the pre-eminence of the HANGER limb in the field of prosthetics.

"no time for nutrition"

All praise to the man who leads a life of unremitting endeavour . . . but what a difficult patient he can be! His refusal to find time for proper feeding habits brings him ultimately to your surgery; yet you may be sure that he will be "far too busy" to carry out any but the simplest nutritional measures you prescribe.

* * *

Fortunately the COMPLEVITE routine is both straightforward and comprehensive. No need to burden the patient with a bewildering array of instructions when two COMPLEVITE tablets (one of each colour) three times daily provide an adequate supplement.

COMPLEVITE TABLETS. *A single supplement for multiple deficiencies, containing vitamins A, B₁, C, D and minerals.*

BASIC PRICE TO N.H.S. — 1000 Tablets 26/9d.

E.2

The most satisfactory antithyroid drug so far available

NEO-MERCAZOLE

- 1) Neo-Mercazole rapidly and effectively controls thyrotoxicosis.
- 2) Neo-Mercazole easily replaces other antithyroid drugs in treatment. Thus, one 50 mg. tablet of methylthiouracil is equivalent to one 5 mg. tablet of Neo-Mercazole.
- 3) Neo-Mercazole is far less likely than other antithyroid drugs to cause side-effects such as skin rashes or joint pains.
- 4) Neo-Mercazole does not significantly alter the size, vascularity or hardness of the gland.

In convalescence

Lethargy and loss of appetite—the very conditions which, in convalescence, it is essential to reverse—are also among the earliest symptoms of Vitamin B deficiency. The administration of B-complex Vitamins to convalescent patients

is, therefore, common expedience. 'Beplex', an established means of providing a balanced dosage of the important B Vitamins, naturally prepared, may be accepted with equal confidence for specific therapy or prophylaxis. It is available as an agreeable elixir or in capsule form to suit the preference of the patient.

IN OCCASIONAL AND CHRONIC CONSTIPATION

“.... reproduction of the physiological process of normal defæcation is of considerable clinical importance”

The above is an extract from the March, 1954 Interim Supplement of the British Encyclopædia of Medical Practice in which the re-educative value of senna is assessed in the treatment of constipation.

The article concludes: “The production of Senokot marks an important pharmacological advance in providing what has hitherto been wanting: a reliable, completely satisfactory preparation of senna, of the greatest value in the treatment of perhaps the commonest of all minor maladies.”

Senokot

REGD

The first stable, standardised
preparation of senna*

HIGH WYCOMBE · BUCKINGHAMSHIRE · ENGLAND

NOW AN ACCEPTED TREATMENT . . .

Transvasin

Contains skin-penetrating esters of salicylic, nicotinic, and p-aminobenzoic acids. It brings real relief to deep-seated muscular rheumatism by simple inunction.

TRANSVASIN, a new preparation developed by Hamol S.A., our Swiss associates, and now available for prescription in this country, contains polar esters of salicylic, p-aminobenzoic and nicotinic acids. These esters readily pass the skin barrier in therapeutic quantities and enable an effective concentration of the drugs to be built up where they are needed. Transvasin not only induces vasodilation of the skin with a superficial erythema, but also brings about a deep hyperaemia of the underlying tissues. It is non-irritant, and can be safely used on the skin.

It is now being widely prescribed, with highly successful results. There is evidence, also, that since a very small quantity is sufficient for each application, the cost of treatment is extremely low:

<i>Salicylic acid tetrahydrofurfuryl-ester</i>	14%
<i>Nicotinic acid ethyl-ester</i>	2%
<i>Nicotinic acid n-hexyl-ester</i>	2%
<i>p-Aminobenzoic acid ethyl-ester</i>	2%
<i>Water-miscible cream base ad</i>	100%

Transvasin is available in 1 oz. tubes at 3/4½ plus 7½d P.T., which are obtainable on form E.C.10, and is not advertised to the public.

Samples and literature will be gladly sent on application.

**6 Gypsona bandages
are needed for
this LEG CAST**

GYPSONA IS RECOGNISED as the most economical plaster of Paris bandage on account of its exceptionally high plaster content. Moreover, every bandage is uniform and it is possible to determine beforehand how many are required for a particular cast.

This leg cast was constructed with three 6" x 3 yds. and three 4" x 3 yds. Gypsona bandages. Two 6" bandages were made into a slab and laid down the back of the leg and

under the sole. The cast was completed with the third 6" bandage encircling the top of the cast and the three 4" bandages around the calf, ankle and foot.

TABILLIN in the new 'Foil-Pac'

This new method
of packing
protects
each tablet
until used

*individually
sealed tablets
—detached
as required*

— a most important consideration in oral penicillin therapy, which is now established as a satisfactory method of systemic administration.

Tabillin offers these advantages:

- 1 Tabillins, being individually sealed, are protected against contamination and loss of potency.
- 2 Each dose of Tabillin is protected until required—therefore superior to liquid preparations.
- 3 Any quantity of Tabillin can be prescribed and dispensed without losing the advantages of individually-sealed protection. Wastage is eliminated.
- 4 Tabillins are supplied in four strengths to facilitate convenient dosage schedules.
- 5 'Foil-Pac' Tabillins are economical. Available at no greater cost than unwrapped tablets.

Whenever Oral Penicillin Therapy is indicated, Tabillin is the preparation of choice.

TABILLIN

Penicillin Tablets B.P.

CHEMOTHERAPY OF TUBERCULOSIS

The concurrent use of PAS salts and Isoniazid is now fully recognized as a major therapeutic measure against all forms of tuberculosis.

'Aminacyl' PAS Salts

'Aminacyl' PAS products, with the exception of the Granulate (Ca PAS only), are available as either Sodium PAS B.P. or as the Calcium Salt.

They include whatever commonly used forms may be prescribed in terms of physicians' choice and patients' preference—

PACKS: Cachets	1.5 g.....	100's	500's
	2.0 g.....	80's	400's
Dragées	0.5 g (plain).....	250's	1,000's
	0.75 g. (enteric-coated)	250's	1,000's
Bulk Powder	1kg.	5kg.
Granulate (Ca PAS)	400 g.	2,000 g.	

'Aminacyl' B-PAS (Calcium + Benzoyl PAS)

This new modification of PAS has the advantage of providing therapeutic effect comparable with that of Na and Ca PAS, but with smaller dosage. Furthermore, it is completely non-toxic, and is almost completely tasteless.

- PACKS:**
- 'Aminacyl' Ca B-PAS Powder: Tins of 150 and 500 envelopes each 3.5 g.
 - 'Aminacyl' Ca B-PAS Cachets: Tins of 80 and 400 × 1 g.
 - 'Aminacyl' Sodium B-PAS Cachets are also available in tins of 80 and 400 × 1.5 g.

'Pasinah' combined PAS/INAH Cachets

for convenient prescription of PAS and Isoniazid concurrently 'PASINAH' Cachets each contain 1.5 g. Na PAS (Sodium p-Aminosalicylate B.P.) and 17 mg. Isonicotinic Hydrazide.

PACKS: Standard Tins of 100 and 500. Details of institutional quantities on request.

Nulacin

MILK-ALKALI DRIP THERAPY WITHOUT INCONVENIENCE OR DISCOMFORT

HERETOFORE, a continuous state of maintained gastric acidity has been possible only with hospitalization and discomfort to the patient. Now, NULACIN will give your patients the relief and comfort of intra-gastric milk-alkali drip therapy without hospitalization, and whether they are at home or at work.

INDICATIONS

NULACIN tablets are indicated whenever neutralization of the gastric contents is required:—in active and quiescent peptic ulcer, gastritis, gastric hyperacidity. Beginning half-an-hour after food, a NULACIN tablet should be placed in the mouth and allowed to dissolve slowly. During the stage of ulcer activity, up to three tablets an hour may be required. For follow-up treatment, the suggested dosage is one or two tablets between meals.

NULACIN tablets are not advertised to the public and have no B.P. equivalent. May be prescribed on E.C.10. The dispensing pack of 25 tablets is free of Purchase Tax. (Price to pharmacists is 2/-) Also available in tubes of 12.

NULACIN tablets are prepared from whole milk combined with dextrans and maltose, and incorporate Magnesium Trisilicate 3.5 grs.; Magnesium Oxide 2.0 grs.; Calcium Carbonate 2.0 grs.; Magnesium Carbonate 0.5 grs.; Ol. Menth. Pip.q.s.

NEW..

for the
 eradication of
Pseudomonas
 Infection in
 Otitis

'AEROSPORIN' brand Otic Solution, which is now available, is a specially formulated preparation of 'Aerosporin' brand Polymyxin B Sulphate, an antibiotic highly and rapidly bactericidal to many gram-negative organisms and pre-eminent against *Pseudomonas pyocyanea*.

'Aerosporin' Otic Solution is therefore of specific value in otitis externa and chronic otitis media due to *Ps. pyocyanea* (*Ps. aeruginosa*). The occurrence of this organism has become more apparent since the introduction of penicillin therapy, which has little or no effect on the gram-negative organisms or the fungi present in otitis. There is evidence that the fungi also are susceptible to 'Aerosporin'. Bacterial resistance to 'Aerosporin' has not been reported.

'Aerosporin' Otic Solution is markedly hygroscopic and has a low surface tension, giving optimal conditions for an adequate concentration of the antibiotic at the site of infection. It is issued in bottles of 10 c.c. with dropper at 9/6, subject to usual discount. Each c.c. contains 10,000 units of polymyxin B sulphate.

BURROUGHS WELLCOME & CO. (The Wellcome Foundation Ltd.) LONDON

rapid response
with **ORAL** antibiotic therapy

Chloromycetin® is unique in being readily and effectively absorbed from the gastro-intestinal tract and producing blood-levels which rise proportionally with increase in dosage. This is a great advantage in severe infections where initially, high blood-levels are essential; a rapid response to treatment is a natural corollary. Owing to effective absorption, gastro-intestinal side-effects following the administration of Chloromycetin are reduced to a minimum.

A new bearing

on Gastro-Enteritis

Emphasis has been given recently to the use of combined chemotherapy in infections and the merit of the judicious combination of antibiotics and sulphonamides in the prevention of bacterial resistance.

In the treatment of many infections of the gastro-intestinal tract, combined therapy with streptomycin and sulphaguanidine is a distinct advance on previous forms of treatment.

Guanimycin, in which oral streptomycin sulphate is combined with sulphaguanidine, is indicated in the treatment of gastro-enteritis, bacillary dysentery, summer diarrhoea, salmonella food poisoning and other mixed infections of the gastro-intestinal tract in infants, children and adults.

Guanimycin is issued as a free-flowing powder from which a smooth, palatable, homogeneous suspension may be made by simple mixture with water.

There is no varied diet problem with Canned Strained Foods

YOU can almost read a mother's thoughts when you recommend early mixed feeding for her baby! Can I get the foods—and prepare them properly? Will it take much time . . . ?

Fortunately, you can tell her about the range of Heinz Strained Foods. It includes chicken and meat broths, soups, vegetables, fruits and cereal—foods often difficult to prepare at home because of time, cost or season.

And these foods actually are even more nutritious than similar foods prepared at home. This is a thing mothers often query, as you know. Foods come fresh to the Heinz factory where they are cleaned, cooked, strained, canned and sterilised immediately, by scientific methods, and inspected at every stage.

Heinz Strained Foods are a balanced team providing vital proteins, vitamins and minerals. Nutritious, hygienic, ready to use, they solve varied diet problems completely and economically.

For a FREE booklet giving the exact nutrient values of these foods, please write to Dept. 4N, H. J. Heinz Company Ltd., Harlesden, London, N.W.10.

NUTRITION

IN HEALTH—

CONVALESCENCE

—SICKNESS

The protein-sparing effect of milk protein is reinforced in St. Ivel (Lactic) Cheese on account of its readily digestible nature and the effect of the Lactobacilli on intestinal flora and pH.

These properties are of great value to the diabetic because this cheese can be consumed in any quantity desired as it contains only a trace of carbohydrate. It makes a valuable and much appreciated contribution to what is often an irksome diet. It helps to keep digestive upsets to a minimum and to enable the patient to obtain full benefit from the other constituents of a restricted diet.

Communications should be addressed to the Director, Central Laboratory, Aplin & Barrett, Ltd., Yeovil, Somerset.

ST. ANDREW'S HOSPITAL FOR NERVOUS AND MENTAL DISORDERS NORTHAMPTON

PRESIDENT: THE EARL SPENCER

MEDICAL SUPERINTENDENT: THOMAS TENNENT, M.D., F.R.C.P., D.P.H., D.P.M.

This Registered Hospital is situated in 130 acres of park and pleasure grounds. Voluntary patients, who are suffering from incipient mental disorders or who wish to prevent recurrent attacks of mental trouble; temporary patients, and certified patients of both sexes are received for treatment. Careful clinical, biochemical, bacteriological, and pathological examinations. Private rooms with special nurses, male or female, in the Hospital or in one of the numerous villas in the grounds of the various branches can be provided.

WANTAGE HOUSE

This is a Reception Hospital in detached grounds with a separate entrance, to which patients can be admitted. It is equipped with all the apparatus for the complete investigation and treatment of Mental and Nervous Disorders by the most modern methods; insulin treatment is available for suitable cases. It contains special departments for hydrotherapy by various methods, including Turkish and Russian baths, the prolonged immersion bath, Vichy Douche, Scotch Douche, Electrical baths, Plombières treatment, etc. There is an Operating Theatre, a Dental Surgery, an X-ray Room, an Ultraviolet Apparatus, and a Department for Diathermy and High-frequency treatment. It also contains Laboratories for biochemical, bacteriological, and pathological research. Psychotherapeutic treatment is employed when indicated.

MOULTON PARK

Two miles from the Main Hospital there are several branch establishments and villas situated in a park and farm of 650 acres. Milk, meat, fruit, and vegetables are supplied to the Hospital from the farm, gardens, and orchards of Moulton Park. Occupational therapy is a feature of this branch, and patients are given every facility for occupying themselves in farming, gardening, and fruit growing.

BRYN-Y-NEUADD HALL

The seaside house of St. Andrew's Hospital is beautifully situated in a park of 330 acres, at Llanfairfechan, amidst the finest scenery in North Wales. On the North-West side of the Estate a mile of sea coast forms the boundary. Patients may visit this branch for a short seaside change or for longer periods. The Hospital has its own private bathing house on the seashore. There is trout-fishing in the park.

At all the branches of the Hospital there are cricket grounds, football and hockey grounds, lawn tennis courts (grass and hard courts), croquet grounds, golf courses, and bowling greens. Ladies and gentlemen have their own gardens, and facilities are provided for handicrafts, such as carpentry, etc.

For terms and further particulars apply to the Medical Superintendent (TELEPHONE: Northampton 4354 (3 lines)), who can be seen in London by appointment.

CLIFFDEN, TEIGNMOUTH

For the early treatment of nervous disorders and patients needing rest and care

A well-appointed House with spacious balconies and extensive views of the South Devon Coast. Beautiful garden and own dairy in 35 acres in the same grounds. ROWDENS, a comfortable house with lovely views. Private road to the beach.

There is also a charming house, EBWORTHY, MANATON, DARTMOOR, situated in 25 acres, 1100 ft. up for bracing moorland air

CHEADLE ROYAL, CHEADLE, CHESHIRE REGISTERED MENTAL HOSPITAL

PRESIDENT: THE RIGHT HON. THE EARL OF DERBY, M.C.

MEDICAL SUPERINTENDENT: W. V. WADSWORTH, B.Sc., M.B., M.R.C.P., D.P.M.

This Hospital receives all types of patients who are suffering from psychological and senile illnesses. It has recently been extensively re-decorated and central heating has been installed throughout, making it one of the most luxuriously appointed hospitals in the country. Private rooms, with special nurses, can be provided. All patients receive very careful and thorough clinical and pathological investigations; the most modern psychiatric treatment is available, including deep insulin therapy. Psychotherapeutic treatment is employed in suitable cases.

Occupational therapy is a special feature of the Hospital and there are excellent facilities for indoor and outdoor recreation—tennis, cricket, croquet, badminton, billiards, cinema, television, etc. Geriatric units for mild cases of senility are provided where patients can pursue as normal a life as possible.

The Hospital is situated in three hundred acres of pleasant Cheshire parkland and yet is only nine miles from Manchester. Glan-y-Don is the Hospital's convalescent home, overlooking the sea at Colwyn Bay. It is extremely comfortable and well appointed and has its own farm and market garden.

For terms and further particulars, apply to the Medical Superintendent. Telephone: GATLEY 2231.

Academic and Educational**ROYAL COLLEGE OF PHYSICIANS OF LONDON**

Dr. ERNEST BASIL VERNY, F.R.C.P., F.R.S., will deliver the BERTRAM LOUIS ABRAHAM LECTURE ON THURSDAY, 8TH JULY, 1954, at 5 P.M. at the College, Pall Mall East, S.W.1.

Subject: "Some Aspects of the Renal Excretion of Water and Salt."

Any member of the Medical Profession admitted on presentation of card.

By order of the President.
HAROLD BOLDERO, Registrar.

UNIVERSITY OF LONDON

A LECTURE entitled "Some Observations of Electrical Activity in Normal and Pathological Muscles" will be given by Prof. A. R. MCINTYRE (Nebraska) at 5.30 P.M. on 8TH JULY at Guy's Hospital Medical School, St. Thomas's-street, London Bridge, S.E.1.

Admission free, without ticket.

JAMES HENDERSON, Academic Registrar.

UNIVERSITY OF DURHAM

KING'S COLLEGE, NEWCASTLE UPON TYNE

COURSES OF INSTRUCTION FOR THE POSTGRADUATE DIPLOMA IN PSYCHOLOGICAL MEDICINE

Part I—A part-time course will be given on 1½ days a week throughout the year, commencing in OCTOBER. Fee £20.

Part II—A full-time 6 months course in Psychiatry and Neurology commences in OCTOBER. Fee £40.

The above courses are integrated with the Newcastle and Sheffield Regional Hospital Board Training Scheme for Psychiatrists. Arrangements can be made for candidates from overseas to complete the requisite clinical experience during the 6 months course.

Separate courses, including clinical experience, are available in Neurology (2 terms; fee £15) and Child Psychiatry (2 months; fee £25).

Further particulars, regulations and syllabus for the Diploma and application forms, may be obtained from the Assistant Registrar, The Medical School, King's College, Queen Victoria-road, Newcastle upon Tyne, 1.

G. R. HANSON, Registrar of King's College.

UNIVERSITY OF EDINBURGH**CHAIR OF PSYCHIATRY**

The University of Edinburgh will shortly proceed to make an appointment to the Chair of Psychiatry which will become vacant on 1st OCTOBER, 1954.

The terms and conditions of appointment may be obtained from the undersigned, with whom applications (8 copies), giving the names of 2 referees and including any testimonials or evidence candidates may wish to offer, should be lodged not later than 15th July, 1954.

Overseas candidates may submit 1 copy of their application which should be received not later than 15th August, 1954.

CHARLES H. STEWART, Secretary to the University.

THE UNIVERSITY OF LEEDS**DIPLOMA IN PSYCHOLOGICAL MEDICINE**

A course for the Diploma in Psychological Medicine will commence in OCTOBER, 1954, if sufficient entries are received. Instruction will be part-time and will occupy 3 half-days a week during 8 academic terms (2½ years).

Further particulars may be obtained from the Sub-Dean, School of Medicine, Leeds, 2, to whom application for admission to the Course should be sent as soon as possible.

SOCIETY OF APOTHECARIES OF LONDON**DIPLOMA IN INDUSTRIAL HEALTH**

The next Examination will begin on MONDAY, 5TH JULY, 1954. The following Examination will be held in December, 1954.

For Regulations apply Registrar, Apothecaries' Hall, Black Friars-lane, London, E.C.4.

**CANCER RESEARCH
M.O. GORDON WILL TRUST**

Clause 11 of the Will of the late Mrs. M. O. Gordon directs her Trustees to apply her residuary Trust Fund for Cancer Research to be made by investigators of either sex selected by her Trustees, such investigators to be graduates in medicine over 21 and British subjects born in Great Britain.

Applications by any persons interested should be addressed to the undersigned before 24th July, 1954, giving qualifications, proposed research, amount of grant required, the period of time for which the grant is to be effective, and references.

GODWIN, BREMRIDGE & Co., Trustees' Solicitors.

8, St. Thomas-street, Winchester.

THE WELSH NATIONAL SCHOOL OF MEDICINE.

(UNIVERSITY OF WALES.) SENIOR LECTURER in the Department of Obstetrics and Gynecology. Apply: Director of Anesthesiology, P.O. Box 115, Cambridge, 38, Massachusetts.

Public Appointments

ANGLESEY. COUNTY OF ANGLESEY. Applications are invited from medical practitioners holding the D.P.H. or similar qualification for the appointment of ASSISTANT COUNTY AND SCHOOL MEDICAL OFFICER AND MEDICAL OFFICER OF HEALTH for the Borough of Beaumaris, the Urban Districts of Llangefni and Menai Bridge and the Rural District of Aethwy. Salary in accordance with the national award for a mixed appointment—£1368 15s., rising to £1687 10s. Starting-point according to experience. The national conditions of service, travelling allowances, &c., apply.

Application forms to be returned to the undersigned by 10th July, 1954, may be obtained from the County Medical Officer, Shire Hall, Llangefni.

WILLIAM JONES, Clerk of the County Council.

Shire Hall, Llangefni.

DERBYSHIRE COUNTY COUNCIL. County Health DEPARTMENT. ASSISTANT MATERNITY AND CHILD WELFARE MEDICAL OFFICER AND SCHOOL MEDICAL OFFICER. Applications are invited from registered medical practitioners for this whole-time superannuable post. Salary £950 p.a. by annual increments of £50 to £1300 p.a., plus a car allowance.

Application forms are obtainable from Dr. J. B. S. MORGAN, County Medical Officer, St. Mary's-gate, Derby, to whom they should be returned by 14th July.

BAHRAIN, PERSIAN GULF. GOVERNMENT OF BAHRAIN MEDICAL DEPARTMENT invites applications from British Women Doctors for the post of ASSISTANT to the Lady Medical Officer in charge of Women's medical services. Age 30-40. Minimum salary £1584, no allowances, rising by annual increments of £45. Starting salary on incremental scale according to age up to 40. Non-contributory gratuity on retirement. Private practice among Europeans only. No income-tax. Agreement for 2 years, renewable by mutual consent. Free quarters with hard furniture and car. Home leave amounts to 2½ months on full pay for every years service. Free return air passage every 2 years.

Applications should be addressed to Messrs. CHAS. KENDALL & PARTNERS LTD., 7, Albert-court, Kensington Gore, London, S.W.7.

BOARD OF CONTROL. Whole-time Deputy Medical SUPERINTENDENT (Consultant), at Rampton Hospital, near Retford, Notts (1143 Beds), for patients exhibiting conduct disorders with mental deficiency. Excellent opportunities for study, treatment and training of behaviour disorders of all kinds and degrees. Applicants must be registered medical practitioners, with experience in psychiatry and the D.P.M.; post is clinical, but experience in hospital administration an advantage; duties may involve attendance at outpatient clinics. Appointment on National Health Service conditions of service and superannuation regulations. House on the estate available at appropriate rental.

Applications, stating name, date and place of birth, nationality, details of education, professional qualifications, war service, present and previous appointments, and names of 3 referees, to Medical Superintendent, Rampton Hospital, Retford, Notts, by 16th July, 1954. Envelopes to be marked A/DMS. Canvassing in any form leads to disqualification. Candidates may visit Hospital by appointment with Medical Superintendent.

HER MAJESTY'S COLONIAL SERVICE. Trinidad. MEDICAL OFFICERS OF HEALTH required. Duties include matters relating to sanitation, public health education, venereal diseases, tuberculosis, maternity and child welfare, school medical work, housing and town planning. Appointment can be made on a permanent basis with pension (non-contributory) at the age of 60, or on short-term agreement. A candidate in the National Health Service may resign from the National Health Service but retain his superannuation rights during his time in the Colonial Service (up to 6 years) and receive a resettlement grant of 20% of the aggregate of his Colonial salary on leaving the Colonial Service at the end of his engagement. Salary scale ranges from B.W.I. \$5280 to B.W.I. \$5760 (£1100-£1200) p.a. A temporary variable cost-of-living allowance is at present payable at the rate of \$108 p.a. (1 B.W.I. \$ equals 4s. 2d.) Starting salary is determined in accordance with the candidate's age, qualifications and experience. A revision of salaries is being undertaken in Trinidad and Officer selected would benefit from any increase granted. Pension is earned at the rate of 1/600th of the final pensionable emoluments for each completed month of service. Provision of quarters not guaranteed, but if government quarters are provided a small rental is charged. Where government quarters are not provided an allowance in lieu is payable. Free passages on first appointment are provided for Officer and family not exceeding 5 persons in all, also free passages on leave subject to a maximum of 3 adult fares. Income-tax at local rates. Local leave is permissible and generous home leave is granted after each tour. Tour of service is 3½ years. Educational facilities are available. Candidates must possess qualification registrable in the United Kingdom and must also hold the Diploma in Public Health.

Application forms can be obtained from the Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith-street, London, S.W.1 (quoting reference No. BCD. 117/38/014).

HER MAJESTY'S COLONIAL SERVICE. Nigeria. A SPECIALIST (Alienist) is required in the Medical Department, Eastern Region, Nigeria. Duties comprise organisation of mental services, training of staff and advising on establishment of new mental hospitals in the Region; investigation, diagnosis and classification of the various forms of mental cases and advice on their treatment and disposal; administration of preventive medicine and clinical work. Appointment, which is for 5 years, may be made as follows:—

(a) From the National Health Service. Candidates may resign from the National Health Service, but retain their superannuation rights during their time in the Colonial Service and receive a resettlement grant of 20% of the aggregate of their Colonial salary on leaving the Colonial Service at the end of their engagement. Salary, including expatriate allowance, amounts to £2025 a year.

(b) On contract with inclusive salary of £2195 a year. On completion of contract a gratuity is paid at the rate of £37 10s. for each completed period of 3 months service (including leave). Extramural Consultant practice permitted under certain conditions.

Tours of service are from 18 to 24 months. Quarters are provided at low rents. Free passages in both directions are provided for officer and his wife. Payment of the cost actually incurred on 1 outward and 1 homeward passage for each of 2 children under age of 18, subject to a maximum of £75 in respect of the return journey for each child, is also granted. Income-tax at local rates. Local leave is permissible and generous home leave is granted after each tour. Candidates must possess a medical qualification registrable in the United Kingdom, and a Diploma in Psychological Medicine, and have had at least 3 years experience in the diagnosis and treatment of mental cases.

Application forms can be obtained from the Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith-street, London, S.W.1 (quoting reference No. BCD. 117/14/025).

COATBRIDGE. BURGH OF COATBRIDGE. Applications are invited from registered medical practitioners possessing the Diploma in Public Health for appointment as ASSISTANT MEDICAL OFFICER OF HEALTH of the Burgh. The salary scale is £950 p.a. rising by annual increments of £50 to £1300 p.a. Placing on the scale may be granted according to qualifications and experience. Main duties will be in respect of Child Welfare, Immunisation and Vaccination Services and such other duties as may be required by the Medical Officer of Health. The post is superannuable and the successful applicant will be required to pass a medical examination.

Applications, giving particulars of qualifications, experience and appointments held, with copies of testimonials, should be lodged with the undersigned within 14 days of the appearance of this advertisement. ALEXANDER S. THOM, Town Clerk. Municipal Buildings, Coatbridge, 14th June, 1954.

DEWSBURY. COUNTY BOROUGH OF DEWSBURY. Applications are invited for the appointment of DEPUTY MEDICAL OFFICER OF HEALTH AND DEPUTY PRINCIPAL SCHOOL MEDICAL OFFICER of the County Borough of Dewsbury. Applicants should be registered medical practitioners and possession of a Diploma in Public Health is desirable but not essential. Preference will be given to candidates approved previously by the Ministry of Education for ascertainment of educationally subnormal children. The salary will be within the scale £1100-£250-£1300 p.a., the commencing salary being fixed in accordance with qualifications and experience, plus a car allowance (at present £108 p.a.). Housing accommodation will be available if required. The appointment is permanent and superannuable and the successful candidate will be required to pass a medical examination.

Particulars of the duties and other conditions of the appointment, together with application forms, may be obtained from the Medical Officer of Health, Municipal Buildings, Halifax-road, Dewsbury, Yorkshire, to whom applications should be sent within 14 days after the appearance of this advertisement. A. NORMAN JAMES, Town Clerk. Town Hall, Dewsbury, 16th June, 1954.

DUBLIN. LOCAL APPOINTMENTS COMMISSION. Medical position vacant. PHYSICIAN (part-time), Limerick Co. Council. Salary: £1000. The duties will be performed mainly in the Regional Hospital, Limerick.

Application forms and particulars from the Secretary, 46, Upper O'Connell-street, Dublin. Latest time for receiving completed application forms 5 P.M. on 9th July, 1954.

DUNDEE. CORPORATION OF DUNDEE. Public Health DEPARTMENT. ASSISTANT MEDICAL OFFICER OF HEALTH (School Health Service). Applications are invited from duly qualified medical practitioners under 45 years of age for the above post. Possession of a D.P.H. or equivalent will be an advantage. The salary will be in accordance with the national scale. The selected candidates will require to pass a medical examination and contribute to the superannuation scheme. The Corporation reserve the right to terminate the appointment of female officers on marriage.

Applications, giving age, qualifications, and experience, and the names of 3 referees, should reach the undersigned on or before 17th July, 1954.

City Chambers, Dundee. ROBERT LYLE, Town Clerk. **FACTORY DOCTORS.** Factories Acts, 1937 and 1948. The following appointment as Appointed Factory Doctor is vacant. Apply to Chief Inspector of Factories, 8, St. James's-square, London, S.W.1.

for Smith Kline & French International Co., owner of the trade mark 'Eskamel'

The test of time

Anusol Haemorrhoidal Suppositories were first introduced forty years ago. During that time they have steadily gained in popularity as a mildly astringent and antiseptic remedy for haemorrhoids and simple ano-rectal inflammations. They meet all the essential requirements — economy in use, ease of insertion, decongestive effect, lubrication, mild antiseptic action and prompt relief without narcotics or analgesics.
